In 6 month old male rats fed for 20 weeks with a low calcium diet containing 0.26 per cent calcium and 0.45 per cent phosphorus a significant reduction in bone mass and in weight of ash from whole bone was recorded (Ferguson and Hartles 1966) Decalcified sections and microradiographs of undecalcified sections from the femur showed no differences from the normal except that the shaft appeared thinner These results are confirmed by those of the present investigation However, as only one observation period was used in the experiment by Ferguson and Hartles (1966) no information was obtained concerning the development of the bone reduction Other investigators (El Maraghi *et al* 1965) found little if any effect on the weight of ash/cm² in the femur in 2 year old rats maintained on a low calcium diet i.e. 0.11 per cent calcium and 0.55 per cent phosphorus for 12 weeks This observation is in agreement with the present results showing that approximately 14 to 16 weeks are required for the development of an evident reduction in bone mass of adult rats fed a similar diet The statement by El Maraghi *et al* (1965) that a dietary calcium concentration of 0.11 per cent would be adequate for maintenance in old rats thus appears to be not valid

Osteoporosis has also been reported in adult cats fed a low calcium high phosphorus meat diet, i.e. calcium 0.007 and phosphorus 0.18 per cent on a wet weight basis (Jowsey and Gershon Cohen 1964) After 10 weeks on this diet radiologic evidence of decreased mineral density was found and microradiographs of undecalcified bone sections showed a reduction in the width of bone trabeculae and the appearance of resorption cavities in the cortical bone The increased resorption was accompanied by an increase in number of newly formed osteones Contrary to the experience in clinical osteoporosis the reduction in bone mass was reversed by feeding a high calcium diet In that experiment and in an extended similar study (Jowsey and Raisz 1968) the induced bone changes were related to observed secondary hyperparathyroidism Cats fed the low calcium meat diet for 5 months showed definite osteomalacia In the present study no such changes were observed during the development of the osteoporosis The appearance of osteomalacia is probably dependent upon degree of calcium deficiency and the dietary calcium phosphorus ratio The osteomalacia reported

by *Jourey and Raisz (1968)* was apparently transient since in rats fed the low calcium diet for 13 months the osteoid borders although highly increased in frequency were of normal width. The decrease in resorption but not in formation observed in such animals treated with a high calcium diet for 1 month suggested that the bone changes induced by the low calcium diet could be reversed. In adult dogs maintained on a low calcium high phosphorus diet bone lesions as in osteitis fibrosa have recently been reported (*Saville andbrook 1968*). Histological examination of decalcified bone sections showed the presence of numerous osteoblasts with the appearance of resorption cavities and further osteoblasts and osteoid tissue covering the surfaces of cancellous bone. Despite the definitely increased amount of osteoid tissue the calcium accretion rate by bone was normal (*Saville andbrook 1968*). This condition suggesting qualitative changes in the bone tissue was called nutritional hyperparathyroidism.

Although prolonged deficiency or malabsorption of calcium has been related to the onset of osteoporosis in humans (*Nordin 1960 1961 1962 1964*) and calcium therapy is widely used in the treatment of the condition the relation of calcium deficiency to osteoporosis is not clear (*Dent and Watson 1966*). Of primary importance in this connection is the observation by *Malm (1958)* that a negative calcium balance prevails in human volunteers for a relatively long time after the institution of a low calcium intake. In a review of the literature it has been stated that osteoporosis can be produced in adult animals by a negative calcium balance usually induced by low calcium diets (*Nordin 1960*). However it was only young growing animals that were studied in these experiments. It is now established that the reaction of the growing skeleton is quite different to that of the mature skeleton. In young rats the bone lesions correspond to those in typical rickets. When there is a rapid reduction in bone mass due to pronounced calcium deficiency osteitis fibrosa or osteomalacia will occur both in growing and in mature animals. In the present investigation the development of osteoporosis is described in mature rats placed on a low calcium diet for varying periods of time from the age of one year. Results of calcium balance studies indicate that the general principle of the adaptation of calcium absorption in old rats can be applied also to other species (*Nicolaysen et al 1953*). The results of the present investigation suggest therefore that prolonged calcium restriction might contribute to the onset of symptomatic osteoporosis in adult humans also.

In lactating female rats a reduction of the bone tissue has been induced by instituting a low calcium diet (Tamlin et al 1953 McCleendon and Blaustein 1965) These changes were described as osteoporosis and could be reversed by the administration of tricalcium phosphate (McCleendon and Blaustein 1965) However, the morphological criteria of osteoporosis used suggest that the condition induced was osteitis fibrosa rather than osteoporosis

In 6 month old male rats fed for 20 weeks with a low calcium diet containing 0.26 per cent calcium and 0.45 per cent phosphorus a significant reduction in bone mass and in weight of ash from whole bone was recorded (Ferguson and Hartles 1966) Decalcified sections and microradiographs of undecalcified sections from the femur showed no differences from the normal except that the shaft appeared thinner These results are confirmed by those of the present investigation However as only one observation period was used in the experiment by Ferguson and Hartles (1966) no information was obtained concerning the development of the bone reduction Other investigators (El Maraghi et al 1965) found little if any effect on the weight of ash/cm³ in the femur in 2 year old rats maintained on a low calcium diet i.e. 0.11 per cent calcium and 0.55 per cent phosphorus for 12 weeks This observation is in agreement with the present results showing that approximately 14 to 16 weeks are required for the development of an evident reduction in bone mass of adult rats fed a similar diet The statement by El Maraghi et al (1965) that a dietary calcium concentration of 0.11 per cent would be adequate for maintenance in old rats thus appears to be not valid

Osteoporosis has also been reported in adult cats fed a low calcium high phosphorus meat diet i.e. calcium 0.007 and phosphorus 0.18 per cent on a wet weight basis (Jowsey and Gershon Cohen 1964) After 10 weeks on this diet radiologic evidence of decreased mineral density was found and microradiographs of undecalcified bone sections showed a reduction in the width of bone trabeculae and the appearance of resorption cavities in the cortical bone The increased resorption was accompanied by an increase in number of newly formed osteones Contrary to the experience in clinical osteoporosis the reduction in bone mass was reversed by feeding a high calcium diet In that experiment and in an extended similar study (Jowsey and Raisz 1968) the induced bone changes were related to observed secondary hyperparathyroidism Cats fed the low calcium meat diet for 5 months showed definite osteomalacia In the present study no such changes were observed during the development of the osteoporosis The appearance of osteomalacia is probably dependent upon degree of calcium deficiency and the dietary calcium phosphorus ratio The osteomalacia reported

rossin no osteoclasts were observed either in the normal or in the osteoporotic animals. Sections of vertebral bone stained with toluidine blue at pH 4.4 showed in the metaphyseal bone areas with evident metachromasia. No difference in the staining properties of these areas was found between normal and osteoporotic animals.

SUMMARY

One year old fully grown rats were maintained on a low calcium diet with normal contents of phosphorus and vitamin D for periods varying from 1 week up to 1 year. The effect of the treatment upon the skeletal tissue was studied by radiographical, microradiographical and histological methods. Quantitation of the amount of bone tissue was performed in special bones by the determination of the 'femur score' and the vertebral bone 'hits'. In special whole bones the contents of ash and hydroxyproline and the gross bone density were examined. The uptake and distribution of chlortetracycline administered by intraperitoneal injection 10 and 20 days before sacrifice was studied in vertebral bone sections.

In the adult rats used the skeletal growth was completed at the start of the experiment. By radiological examination performed at the start and at the end of each experimental period, the occurrence of a slight but definite reduction of the cortical thickness of the tubular bones and a decreased density of the trabecular pattern in the metaphyseal bone was found in all animals fed the low calcium diet for 6 months and longer. These osteoporotic rats showed significantly lower values for the femur score and the vertebral bone hits than for the normal controls. The ash content of the tibia and the hydroxyproline content of the metacarpal bone showed significantly decreasing values during the observation period. The six groups of rats kept on a restricted calcium intake for 6 to 12 months showed significantly lower values for the gross bone density of the humerus on comparison with those of the normal controls. On microradiographical examination a reduction in the number of vertebral bone trabeculae was observed in the rats fed the low calcium diet for 6 months and longer. The remaining bone trabeculae were considerably thinner than normal but no change in degree of mineralization was observed, the bone being as evenly mineralized as in the normal rats. In these osteoporotic rats the tetracycline fluorescent micrographs had a similar appearance to those in normal rats. Thus no apparent difference in the amount of bone surfaces showing fluorescence of newly formed bone was observed. On histological examination of decalcified sections stained with haematoxylin

eosin no osteoclasts were observed either in the normal or in the osteoporotic animals. Sections of vertebral bone stained with toluidine blue at pH 4.4 showed in the metaphyseal bone areas with evident metachromasia. No difference in the staining properties of these areas was found between normal and osteoporotic animals.

Studies on the Development of Experimental Osteoporosis

II The Effect of Prolonged Calcium Restriction on the Blood
Calcium Level and the Distribution of Ca^{45} between Blood and
Bone in Adult Male Rats

by

Sven Erik Larsson

is longer for old than for young rats (Henry *et al* 1960) According to Nicolaysen *et al* (1953) a marked adaptation i.e. a distinctly increased efficiency of calcium absorption will occur in old rats only when they have suffered a substantial loss of calcium from the skeleton in principle this finding agrees with observations in man It has been considered that the increased efficiency of calcium absorption would compensate fully for any previous loss (Nicolaysen *et al* 1953) However in a previous study (Larsson 1969 a) the development of a significant reduction in bone mass was found in adult male rats maintained on a prolonged low calcium intake for varying periods of up to one year Histological examination revealed that the bone changes induced in these animals fulfilled the criteria for osteoporosis described by Collins (1966)

The present investigation was undertaken in order to elucidate the pathomechanisms involved during the development of this type of osteoporosis The study presented here concerns the effect of prolonged calcium restriction in adult male rats on the blood calcium level and the distribution of Ca^{45} between blood and bone after intraperitoneal administration of the isotope

EXPERIMENTAL

The same experimental material was used as in the previous investigation (Larsson 1969 a) A total of 90 adult male rats of the Sprague Dawley strain¹ were divided into two experimental series Sixty animals comprised a short term and 35 a long term series Apart from the duration of the test diets both series were treated identically All animals except the controls of the long term series (see below) were stated to be 12 to 12½ months old at the start of the experiment The mean initial body weight of the animals of the two series was 499.0 ± 5.2 and 501.8 ± 9.2 grams respectively The animals had been bred on a standard laboratory ration containing 1.4 per cent Ca and 1.2 per cent P² and adequate amounts of vitamin D

Experimental animals

All the experimental animals were fed the low calcium test diet of General Biochemical Inc. Champaign, Ohio The ingredients and composition of this diet have been described in a previous investigation (Larsson 1969 a) Chemical

INTRODUCTION

In human osteoporosis disturbances in calcium metabolism and the efficiency of calcium homeostasis in maintaining extracellular fluid calcium has been considered to be of major pathophysiological importance for the reduction of bone mass (*Heaney 1965*) in contradistinction to the concept of a primary defect (accelerated ageing of bone) in the bone tissue itself (*Urist 1962*) Studies in osteoporotic patients with bone seeking isotopes have contributed little to our understanding of the osteoporotic process (*Nordin 1962*) Normal skeletal accretion of bone seeking isotopes or stable strontium is generally reported (*Heaney and Whedon 1958, Dow and Stanbury 1960 Fraser et al 1960 Nordin 1960 Dymling 1964*) but both reduced accretion (*Bauer et al 1957, Eisenberg and Gordan 1961 Dymling 1962 Bronner et al 1963 Lafferty et al 1964*) and increased (*Nordin 1959*) have also been observed However a reduced accretion by the skeleton in osteoporosis may be relative due to reduced bone mass Usually clinical osteoporosis takes several years to develop until the disease can be diagnosed and from results of isotope studies in the osteoporotic patient it is difficult therefore to draw any conclusions concerning the patho mechanisms involved during this prolonged process of bone reduction

Available data obtained from studies with bone seeking isotopes are inconclusive with regard to the skeletal reaction to prolonged calcium restriction in experimental animals A greater retention than normal of a dose of strontium has been reported in calcium deficient young rats (*Harrison and Fraser 1960*) However since the calcium deficient animals failed to grow or to gain weight at the same rate as the control animals it is difficult to interpret the results obtained These findings were not confirmed by *Copp and Suker (1962)* who observed a reduced retention of Ca^{45} in young rats after dietary calcium restriction In calcium deficient adult rats their data indicated normal Ca^{45} retention and increased bone resorption In calcium deficient pregnant rats the percentage of orally administered Ca^{45} retained has been reported to be 3.5 to 4.0 times that retained by control animals (*Bawden and Osborne 1962*)

The adaptation to a reduced calcium intake has been extensively investigated by balance studies in the rat (*Henry and Kon 1947 1953 Barucha and McCay 1954 Nicolajsen 1943 1956 Henry et al 1960*) Old rats need a minimum of 4 months to adapt themselves to a low calcium intake This period of adaptation

Plasma sampling

Blood was collected from all animals at the time of sacrifice which was performed by bleeding the animal to death from the femoral artery under ether anaesthesia. In addition from the animals in the long term series 0.3 to 0.4 ml tail blood was collected at intervals of 12, 24, 36 and 48 hours following the administration of the isotope. The collected blood was centrifuged immediately at 3000 rpm for 15 minutes and the supernatant plasma was pipetted into acid washed test tubes and kept at -20°C pending subsequent analyses.

Bone sampling

In the animals of the long term series the right fore paw was removed under light ether anaesthesia 24 hours and the left one 48 hours after the Ca^{45} administration. The specimens were then kept at -20°C for subsequent determination of the Ca^{45} activity of the second metacarpal bone. The animals were relatively unaffected by the operations. After sacrifice both tibiae of the animals of the short term series and the right tibia and the right fifth metatarsal bone of those of the long term series were taken for isotope studies.

Preparation of material for Ca^{45} activity determinations

A Whole bone The following bones were carefully freed of surrounding soft tissues and periosteum: a) both tibiae in the animals of the short term series but only the right one in the long term series; b) in the animals of the long term series in addition the right and the left second metacarpal bone and the right fifth metatarsal bone were used.

B Pure cortical bone tissue In the animals of the long term series the tubular bones except the right tibia and humerus were carefully dissected free from soft tissues and periosteum. The ends of the bones and the articular cartilage were removed using a bandsaw. The diaphyses were split into small bone fragments which were carefully cleaned of all bone marrow, no solvents being used. The bone fragments were defatted and dehydrated in 5 changes of acetone for 3 days. This material was finally air dried and then pulverized using an Intermediate model Wiley Laboratory Mill provided with a 60 mesh sieve. The whole bones and approximately 75 mg of cortical bone powder of all specimens of each series were ashed simultaneously in a muffle furnace at 700°C for 16 hours. The exact weight of the ash was determined with the aid of a Mettler balance and with an accuracy of 0.5 mg. The ash of the whole tibia

analyses showed that the diet contained 0.09 per cent Ca and 0.55 per cent P. The Ca/P ratio was 1.6:1. The diet was supplied with an adequate amount of vitamin D. All animals received diet and deionized water *ad libitum*. The daily calcium intake was estimated at 18–20 mg per animal. Groups of 5 rats each were kept on this regimen for different periods of time: in the short term series ten groups for 1 to 16 weeks; in the long term series six groups for 6 to 12 months.

Another group of 5 animals was fed the test diet described above supplemented with 4 per cent CaCO_3 ; i.e. this diet contained a total amount of 1.7 per cent Ca and 0.55 per cent P. The Ca/P ratio was 1.0:4. This diet and tap water were given *ad libitum* for 16 weeks and the daily calcium intake of these animals was estimated at 340–360 mg.

Control animals

In the short term series one group of 5 rats received a normal laboratory ration¹ containing 1.0 per cent Ca and 0.75 per cent P for 16 weeks. The Ca/P ratio was 1.0:7.5. Diet and tap water were given *ad libitum*. The daily calcium intake was estimated at 200–220 mg. In the long term series one group of 5 animals was fed the normal laboratory ration and tap water for 4 weeks to accustom the animals to the laboratory routine. These animals were stated to be approximately 20 months old when delivered to the laboratory.

All the animals were housed five to each cage without access to direct sunlight and at a temperature of 18–20°C. The animals moved about freely in the cages. No coprophagy was observed. The series were planned in such a way that all the animals within each series were sacrificed at the same time. In all animals the initial and final body weights were recorded. In addition all the animals of the short term series were weighed weekly.

Isotope administration

Seventy-two hours before sacrifice each animal was injected intraperitoneally with 20 microcuries of Ca^{45} in 1.0 ml physiological saline solution from a single batch of Ca^{45}Cl for each series.

Plasma sampling

Blood was collected from all animals at the time of sacrifice which was performed by bleeding the animal to death from the femoral artery under ether anaesthesia. In addition from the animals in the long term series 0.3 to 0.4 ml tail blood was collected at intervals of 12, 24, 36 and 48 hours following the administration of the isotope. The collected blood was centrifuged immediately at 3000 rpm for 15 minutes and the supernatant plasma was pipetted into acid washed test tubes and kept at -20°C pending subsequent analyses.

Bone sampling

In the animals of the long term series the right fore paw was removed under light ether anaesthesia 24 hours and the left one 48 hours after the Ca^{45} administration. The specimens were then kept at -20°C for subsequent determination of the Ca^{45} activity of the second metacarpal bone. The animals were relatively unaffected by the operations. After sacrifice both tibiae of the animals of the short term series and the right tibia and the right fifth metatarsal bone of those of the long term series were taken for isotope studies.

Preparation of material for Ca^{45} activity determinations

A. Whole bone The following bones were carefully freed of surrounding soft tissues and periosteum: a) both tibiae in the animals of the short term series but only the right one in the long term series; b) in the animals of the long term series in addition the right and the left second metacarpal bone and the right fifth metatarsal bone were used.

B. Pure cortical bone tissue In the animals of the long term series the tubular bones except the right tibia and humerus were carefully dissected free from soft tissues and periosteum. The ends of the bones and the articular cartilage were removed using a bandsaw. The diaphyses were split into small bone fragments which were carefully cleaned of all bone marrow, no solvents being used. The bone fragments were defatted and dehydrated in 5 changes of acetone for 3 days. This material was finally air dried and then pulverized using an Intermediate model Wiley Laboratory Mill provided with a 60-mesh sieve. The whole bones and approximately 75 mg of cortical bone powder of all specimens of each series were ashed simultaneously in a muffle furnace at 700°C for 16 hours. The exact weight of the ash was determined with the aid of a Mettler balance and with an accuracy of 0.05 mg. The ash of the whole tibia

was dissolved in 50 ml of 12 N hydrochloric acid. When the ash was completely dissolved, deionized water was added to the solution to a final volume of 100 ml. An aliquot of 20 ml was pipetted into a 25 ml polyethylene counting vial which was then filled with a gel scintillator composed of 2.5 Diphenylloxazole (PPO) 1.0 g 1,4-bis(2-(4-Methyl-5-Phenyl-oxazolyl)) Benzene (POPOP) 0.3 g Naphthalene 100.0 g Dioxane 1 litre and thixotropic gel powder (CAB O SIL) to saturation. The ash of the small bones and the ash of the cortical bone powder were dissolved directly in 20 ml of 12 N hydrochloric acid in the counting vials and counting was performed after addition of the scintillator.

C Plasma The Ca^{45} activity was determined directly using 10 ml of plasma collected at sacrifice and about 0.2 ml of plasma obtained from the blood collected from the tail at different intervals after the administration of the isotope. This procedure was considered suitable for the purpose of the present study (see *Budy* 1963) and was recommended by *Lumir* (1966). The same scintillator was used as for the bone ash solutions.

ANALYTICAL METHODS

*Determination of the Ca^{45} activity*¹ was carried out in a Packard Tri Carb Liquid Scintillation Spectrometer. This counting was performed at +3°C simultaneously for all the specimens within each series. The samples were usually counted 3 × 5 minutes each at least 10 000 impulses being recorded. The background was of the magnitude of 25 to 30 c.p.m. The coefficient of variation for the quotient between the two energy channels used was 2.8 to 3.2 per cent. The stability of the spectrometer was tested as follows. One Ca^{45} sample was counted 60 times during a period of about 15 hours. The coefficient of variation was 1.0 per cent, i.e. the stability of the apparatus was good. Corrections were made for background and decay. Corrections for self absorption were not considered necessary because of the constancy of counting efficiency.

¹) The method for determination of the Ca^{45} activity as used in the Orthop Res labor Presbyterian St Luke's Hosp, Chicago Ill has been applied in this investigation.

) Model 314 EX 2 Packard Instruments Co. L1 Grange Ill USA

The calcium content of cortical bone powder was analysed by atomic absorption spectrophotometry with the aid of a Perkin Elmer Model 303 Instrument. About 50 mg of bone powder were ashed as described above. The ash was weighed on a Mettler balance and then dissolved in 10 ml of 1.2 N hydrochloric acid. After dilution with deionized water to the desired calcium concentration a 5 per cent lanthanum solution in 25% (v/v) HCl was added so that the final calcium concentration was within an optimum working range of 1 to 10 ppm and with 0.5 per cent lanthanum¹. In this way the calcium/lanthanum ratio was 1:1000 as recommended by Willis (1961) for suppression of the interference by phosphorus with the solution. The added calcium recovery in these bone ash solutions was found to be 98 per cent. Duplicate determinations were performed throughout. The coefficient of variation for these analyses was less than 1 per cent.

The calcium concentration of plasma obtained from the blood collected at sacrifice was determined by flame photometry using an Eppendorf's photometer. Duplicate determinations were always performed. The error of the method was less than 1 per cent (Johansson 1966).

Treatment of isotope data The Ca^{45} activity of bone was expressed as counts per minute per milligram of ash. No significant difference was found in the calcium contents of ash from pure cortical bone tissue of the normal and of the calcium deficient animals: the mean calcium concentration was 38.09 ± 0.20 per cent. Therefore the expression counts per minute per milligram of ash is equivalent to the specific activity and the factor 0.3809 was used when the bone accretion rates were calculated (see below). The Ca^{45} activity of plasma at 72 hours after the isotope injection was expressed as counts per minute per milligram of calcium. The plasma Ca^{45} activity curves (Fig. 3) were also based upon values expressed as counts per minute per milligram of calcium. Because of the necessity of collecting as little blood as possible at the different periods after the Ca^{45} administration plasma calcium determinations were performed only on blood samples obtained at sacrifice.

The calcium accretion rates for the whole tibia (mg calcium/hour/mg calcium of the tibia) were calculated according to Bauer et al. (1955). The mean values within each group were used throughout.

¹) Perkin Elmer Review May 1966

was dissolved in 50 ml of 12 N hydrochloric acid. When the ash was completely dissolved, deionized water was added to the solution to a final volume of 100 ml. An aliquot of 20 ml was pipetted into a 25 ml polyethylene counting vial which was then filled with a gel scintillator composed of 2.5 Diphenyloxazole (PPO) 1.0 g 1,4-bis(2-(4-Methyl-5-Phenyloxazolyl)) Benzene (POPOP) 0.3 g Naphthalene 100.0 g Dioxane 1 litre and thixotropic gel powder (CAB O SIL) to saturation. The ash of the small bones and the ash of the cortical bone powder were dissolved directly in 20 ml of 12 N hydrochloric acid in the counting vials and counting was performed after addition of the scintillator.

C Plasma: The Ca^{45} activity was determined directly, using 1.0 ml of plasma collected at sacrifice and about 0.2 ml of plasma obtained from the blood collected from the tail at different intervals after the administration of the isotope. This procedure was considered suitable for the purpose of the present study (see *Budy* 1963) and was recommended by *Kumar* (1966). The same scintillator was used as for the bone ash solutions.

ANALYTICAL METHODS

*Determination of the Ca^{45} activity*¹ was carried out in a Packard Tri Carb Liquid Scintillation Spectrometer. This counting was performed at $+3^\circ\text{C}$ simultaneously for all the specimens within each series. The samples were usually counted 3×5 minutes each, at least 10,000 impulses being recorded. The background was of the magnitude of 25 to 30 c.p.m. The coefficient of variation for the quotient between the two energy channels used was 2.8 to 3.2 per cent. The stability of the spectrometer was tested as follows. One Ca^{45} sample was counted 60 times during a period of about 15 hours. The coefficient of variation was 1.0 per cent, i.e. the stability of the apparatus was good. Corrections were made for background and decay. Corrections for self absorption were not considered necessary because of the constancy of counting efficiency.

The calcium content of cortical bone powder was analysed by atomic absorption spectrophotometry with the aid of a Perkin Elmer Model 303 Instrument. About 50 mg of bone powder were ashed as described above. The ash was weighed on a Mettler balance and then dissolved in 10 ml of 12 N hydrochloric acid. After dilution with deionized water to the desired calcium concentration a 5 per cent lanthanum solution in 25 % (v/v) HCl was added so that the final calcium concentration was within an optimum working range of 1 to 10 ppm and with 0.5 per cent lanthanum¹. In this way the calcium/lanthanum ratio was 1:1000 as recommended by Willis (1961) for suppression of the interference by phosphorus within the solution. The added calcium recovery in these bone ash solutions was found to be 98 per cent. Duplicate determinations were performed throughout. The coefficient of variation for these analyses was less than 1 per cent.

The calcium concentration of plasma obtained from the blood collected at sacrifice was determined by flame photometry using an Eppendorf's photometer. Duplicate determinations were always performed. The error of the method was less than 1 per cent (Johansson 1966).

Treatment of isotope data. The Ca^{45} activity of bone was expressed as counts per minute per milligram of ash. No significant difference was found in the calcium contents of ash from pure cortical bone tissue of the normal and of the calcium deficient animals: the mean calcium concentration was 38.09 ± 0.20 per cent. Therefore the expression counts per minute per milligram of ash is equivalent to the specific activity and the factor 0.3809 was used when the bone accretion rates were calculated (see below). The Ca^{45} activity of plasma at 72 hours after the isotope injection was expressed as counts per minute per milligram of calcium. The plasma Ca^{45} activity curves (Fig. 3) were also based upon values expressed as counts per minute per milligram of calcium. Because of the necessity of collecting as little blood as possible at the different periods after the Ca^{45} administration plasma calcium determinations were performed only on blood samples obtained at sacrifice.

The calcium accretion rates for the whole tibia (mg calcium/hour/mg calcium of the tibia) were calculated according to Baker *et al.* (1955). The mean values within each group were used throughout.

¹) Perkin Elmer Review May 1966

Statistical treatment of data The analytical data obtained from the rats in each group were subjected to analysis of variance with one-way layout according to *Scheffe* (1961) The hypothesis of no difference between groups was tested at the 5 per cent significance level When a significant result was obtained data for one or more groups were combined in order to find significant contrasts These were tested according to *Scheffe* (1961) The hypothesis of no difference between the data of the group of rats fed the calcium enriched diet and those of the normal control group in the short term series was tested with Student's *t* test as described by *Brownlee* (1965) A 5 per cent significance level was used In the present study the term significant stands for statistically significant as found with the tests described above

RESULTS

Six deaths occurred among the whole material five among the experimental animals in the long term series and one in the short term series all probably due to advanced age These animals were excluded The remaining animals were in good health The body weights have been reported in a previous study (*Larsson* 1969 a) on the same material

Fig. 1 Plasma calcium in rats fed the normal laboratory ration the calcium enriched diet and the low calcium diet

Plasma calcium (Fig 1 Table 1)

The *t* was no significant difference in plasma calcium between the normal control animals of the short term and the long term series. The animals fed the calcium enriched diet for 16 weeks showed similar values to those of the control animals. In the rats maintained on the low calcium diet for 1, 2, 3 and 4 weeks subnormal values were noted. This fall in plasma calcium was however not significant. In the five groups of rats maintained on a low calcium diet for 5 to 14 weeks normal plasma calcium values were observed. Subnormal values were again noted in the animals fed the low calcium diet for 4, 6 and 7 months. Neither was this fall in plasma calcium significant. In the four groups

Table 2 Plasma Ca specific activity 72 hours after the intraperitoneal injection of 20 microcuries of Ca⁴⁵ per animal in rats fed the normal laboratory ration the low calcium diet and the calcium enriched diet

1 week showed significantly increased values compared with those of the rats fed the normal laboratory ration. The animals fed the low calcium diet for 3 to 5 weeks showed approximately the same values as those of the normal controls. Significantly higher values were noted in animals maintained on a restricted calcium intake for 8 weeks to 1 year. This difference was most pronounced in the groups treated for 6 to 12 months. The rats fed the calcium enriched diet for 16 weeks showed significantly lower values compared with those of the normal controls.

of animals maintained on the low calcium diet for 8 to 12 months the plasma calcium showed no significant change. The reductions in plasma calcium amounted to approximately 12 per cent in the groups of rats kept on the low calcium diet for 2 weeks and 6 and 7 months.

The plasma Ca^{45} specific activity at 72 hours after the Ca^{45} injection (Fig 2 Table 2)

The values of the two control groups fed the normal laboratory ration showed no significant difference. The group of rats kept on a low calcium intake for

values were significantly higher at all periods after the Ca^{45} injection in all the experimental groups and showed a slight increase with time after the isotope injection. In contrast the values obtained from the rats of the control group showed a slight decrease progressing with time after the injection of the isotope.

The Ca^{45} activity of the tibia 72 hours after the Ca^{45} injection (Fig 5 Table 4)

The values of the two groups of rats fed the normal laboratory ration showed no significant difference.

In the rats fed the low calcium diet for 1 to 4 weeks successively higher values were found compared with those of the normal controls with a maximum increase by approximately 100 per cent in the 3rd and 4th weeks. In the

Fig. 5 The uptake of Ca^{45} in the tibia 72 hours after the intraperitoneal administration of 2 mic ocuries of Ca^{45} in rats fed the normal laboratory ration, the calcium enriched diet and the low calcium diet.

The plasma Ca^{45} activity at different periods after the Ca^{45} injection was examined in the long term series (Fig 3) All groups maintained on prolonged calcium restriction showed consistently higher values than those of the control group The Ca^{45} activity showed throughout a decrease with time after the injection, which was more rapid for the control group than for the experimental groups

The Ca^{45} activity of small bones at different periods after the Ca^{45} injection was also examined in the long term series (Fig 4 Table 3) In all experimental groups consistently higher values were obtained than in the control group The

Table 4 The Ca^{45} uptake of the tibia (cpm/mg ash) 72 hours after the intraperitoneal injection of 20 microcuries of Ca^{45} per animal in rats fed the normal laboratory ration the low calcium diet and the calcium enriched diet

The calcium accretion rate for the tibia (Table 6)

The accretion rate (mg calcium/hour/mg calcium of the tibia) was examined in the rats of the long term series. In the group of rats fed the low calcium diet for 6 months the mean accretion rate was lower than in the control group. The four groups of animals maintained on a low calcium intake for 7 to 10 months showed approximately the same mean values as for the control group. Finally a lower accretion rate was found in the group of rats kept on a restricted calcium intake for 12 months compared with that in the control group.

Groups	ACCRETION RATE

12	7.69×10^{-3}	

Table 6. The mean calcium accretion rate for the tibia in rats fed the normal laboratory ration and the low calcium diet.

DISCUSSION

Material from the same animals was studied in a previous investigation and it was then found that there was no significant difference in femur length between normal and experimental animals and that the skeletal growth and calcification were completed in these rats. The degree of mineralization studied by microradiography of undecalcified sections of vertebral bone was the same in normal and osteoporotic animals (Larsson 1969 a).

following 5 to 6 week groups the Ca^{45} uptake was increased by approximately 60 per cent. The increased Ca^{45} uptake observed between the 3rd and the 16th week of treatment was statistically significant. The six groups of rats kept on a restricted calcium intake for 6 to 12 months showed a consistently increased isotope uptake by the tibia by approximately 40 per cent of that of the control group. When the combined values of all these groups were compared with the control group the increase was found to be significant. The animals fed the calcium enriched diet for 16 weeks showed a significantly decreased Ca^{45} uptake compared with that of the control animals.

The Ca^{45} activity of cortical bone 72 hours after the Ca^{45} injection (Table 5)

The Ca^{45} uptake was further examined in cortical bone powder obtained from the rats of the long term series. In the rats maintained on the low calcium diet for 6 to 9 months the values obtained were approximately 20 per cent higher than in the normal control group. The two groups of animals fed the low calcium diet for 10 and 12 months showed only slightly higher values than those of the control group.

(Copp *et al* 1960) is exquisitely well regulated by means of a negative feedback (McLean and Urist 1955). Normally the strain of rats used in the present study shows a markedly constant blood calcium. During an 8 week period 8 adult normal male rats showed a blood calcium concentration of $4.8 - 4.9 \text{ mEq/l}$ and the standard error of the mean with the same analytical method used in the present investigation ranged from $0.02 - 0.06$ (Johansson 1966). Eventual seasonal variations as reported by Biering (1950) were eliminated in the present study since all blood samples were collected and analyses were performed on all animals within each experimental series at the same time. Neither was there any significant difference in the blood calcium level of the control groups of each series. In short term infusion experiments on dogs an attempt was made to evaluate quantitatively the effectiveness of negative feedback in regulating blood calcium. The findings in those experiments support the view that the constancy of blood calcium is not due to an extremely efficient homeostatic regulation but must result in part from the relatively small stresses positive or negative calcium loads which are normally placed upon the system (Hausmann and Riggs 1966). The recurrent decreases in the blood calcium level observed at different periods of time in the present investigation and which were followed by normalization were probably due to the large stresses induced by the prolonged calcium restriction upon the mechanisms involved in blood calcium regulation.

Low calcium diets with a high phosphorus content have been reported to result in a fall of the blood calcium in different species e.g. adult dogs (Saville and Krook 1968), adult cats (Jowsey and Raisz 1968) and adult rats (Engfeldt *et al* 1954). In the present investigation it was found that the restriction of calcium alone with an adequate supply of phosphorus and vitamin D also causes a reduction of the blood calcium level. It is well known that there is a relationship between dietary levels of calcium and phosphorus and the parathyroids and further between high blood phosphorus concentration and depressed blood calcium although the exact mechanism of these effects is not clear (Nordin 1961). However decreased blood calcium has been reported in different species after institution of low calcium diets with very varying Ca/P ratios such as e.g. 1/45 (Jowsey and Raisz 1968), 1/16 (Engfeldt *et al* 1954), 1/10 (Saville and Krook 1968), 1/6.1 (the present investigation) and 1/15 (Campbell and Douglas 1963). With regard to the relation between reduced calcium intake and the development of osteoporosis in humans it is of interest that a slight fall in the blood calcium level occurs at different periods of time in adult rats during prolonged calcium restriction when the diet is normal in phosphorus and vitamin D. It is likely that this also occurs when the low

Although there is usually no abnormality in blood biochemistry in clinical osteoporosis disturbances in calcium metabolism and the efficiency of calcium homeostasis in maintaining extracellular fluid calcium have been considered as the primary pathomechanism for the development of osteoporosis in humans (Heaney 1965). In this respect, it was considered of great interest to follow the changes in the blood calcium level and the distribution of Ca^{45} between blood and bone during the development of osteoporosis induced in these adult rats by prolonged calcium restriction. It has been reported earlier that old rats need a minimum of 0.5 per cent calcium in the diet for equilibrium (Henry and Lon 1947). By feeding a diet containing 0.13 per cent calcium and 0.38 per cent phosphorus old rats remain in negative calcium balance for at least 4 months (Henry *et al.* 1960). In the present study adult male rats were maintained on a similar low calcium diet containing 0.09 per cent calcium and 0.55 per cent phosphorus with adequate amounts of vitamin D for periods varying from 1 week up to 12 months. Because of this restriction of the calcium intake the animals treated for 14 to 16 weeks and longer developed significant skeletal changes characteristic of osteoporosis (Larsson 1969 a).

It was found in the present study that during the development of osteoporosis slightly subnormal blood calcium values appeared not only initially but also at later periods of time with normalized values meanwhile. Corresponding to the transient initial fall in blood calcium induced in the present investigation by changing from a normal to a low calcium intake subnormal blood calcium has been reported in healthy humans also after instituting a low calcium diet (Nordin 1964, MacFadyen *et al.* 1965, Nordin *et al.* 1965). This fall of the blood calcium level is certainly due to the large stresses upon the mechanisms involved in blood calcium regulation during a period of negative calcium balance. The hypocalcemia of calcium deprivation in humans is believed to be transient and very small changes in blood calcium concentration are considered to be corrected by bone mineral without the intervention of the parathyroid glands due to the existence of a genuine steady state between bone mineral and tissue fluid (Nordin *et al.* 1965). However the results of the present study indicate that subnormal blood calcium values occur at different periods of time during prolonged calcium restriction and that these changes are relatively slowly corrected by bone mineral (see below). The falls in the blood calcium level recorded in the present investigation were further of such a magnitude that stimulated parathyroid activity might have been involved for the normalization of the blood calcium concentration.

Under normal circumstances the well documented constancy of blood calcium

(Copp *et al* 1960) is exquisitely well regulated by means of a negative feedback (McLean and Urist 1955). Normally the strain of rats used in the present study shows a markedly constant blood calcium. During an 8 week period 8 adult normal male rats showed a blood calcium concentration of $4.8-4.9$ mEq/l and the standard error of the mean with the same analytical method used in the present investigation ranged from $0.02-0.06$ (Johansson 1966). Eventual seasonal variations as reported by Biering (1950) were eliminated in the present study since all blood samples were collected and analyses were performed on all animals within each experimental series at the same time. Neither was there any significant difference in the blood calcium level of the control groups of each series. In short term infusion experiments on dogs an attempt was made to evaluate quantitatively the effectiveness of negative feedback in regulating blood calcium. The findings in those experiments support the view that the constancy of blood calcium is not due to an extremely efficient homeostatic regulation but must result in part from the relatively small stresses positive or negative calcium loads which are normally placed upon the system (Hausmann and Riggs 1966). The recurrent decreases in the blood calcium level observed at different periods of time in the present investigation and which were followed by normalization were probably due to the large stresses induced by the prolonged calcium restriction upon the mechanisms involved in blood calcium regulation.

Low calcium diets with a high phosphorus content have been reported to result in a fall of the blood calcium in different species e.g. adult dogs (Sasille and Arook 1968), adult cats (Jousey and Raisz 1968) and adult rats (Engfeldt *et al* 1954). In the present investigation it was found that the restriction of calcium alone with an adequate supply of phosphorus and vitamin D also causes a reduction of the blood calcium level. It is well known that there is a relationship between dietary levels of calcium and phosphorus and the parathyroids and further between high blood phosphorus concentration and depressed blood calcium although the exact mechanism of these effects is not clear (Nordin 1961). However decreased blood calcium has been reported in different species after institution of low calcium diets with very varying Ca/P ratios such as e.g. 1/45 (Jousey and Raisz 1968), 1/16 (Engfeldt *et al* 1954), 1/10 (Sasille and Arook 1968), 1/6.1 (the present investigation) and 1/15 (Campbell and Douglas 1965). With regard to the relation between reduced calcium intake and the development of osteoporosis in humans it is of interest that a slight fall in the blood calcium level occurs at different periods of time in adult rats during prolonged calcium restriction when the diet is normal in phosphorus and vitamin D. It is likely that this also occurs when the low

Although there is usually no abnormality in blood biochemistry in clinical osteoporosis disturbances in calcium metabolism and the efficiency of calcium homeostasis in maintaining extracellular fluid calcium have been considered as the primary pathomechanism for the development of osteoporosis in humans (Heaney 1965). In this respect, it was considered of great interest to follow the changes in the blood calcium level and the distribution of Ca^{45} between blood and bone during the development of osteoporosis induced in these adult rats by prolonged calcium restriction. It has been reported earlier that old rats need a minimum of 0.5 per cent calcium in the diet for equilibrium (Henry and Aon 1947). By feeding a diet containing 0.13 per cent calcium and 0.38 per cent phosphorus old rats remain in negative calcium balance for at least 4 months (Henry *et al* 1960). In the present study adult male rats were maintained on a similar low calcium diet containing 0.09 per cent calcium and 0.55 per cent phosphorus with adequate amounts of vitamin D for periods varying from 1 week up to 12 months. Because of this restriction of the calcium intake the animals treated for 14 to 16 weeks and longer developed significant skeletal changes characteristic of osteoporosis (Larsson 1969 a).

It was found in the present study that during the development of osteoporosis slightly subnormal blood calcium values appeared not only initially but also at later periods of time with normalized values meanwhile. Corresponding to the transient initial fall in blood calcium induced in the present investigation by changing from a normal to a low calcium intake subnormal blood calcium has been reported in healthy humans also after instituting a low calcium diet (Nordin 1964 MacFadyen *et al* 1965 Nordin *et al* 1965). This fall of the blood calcium level is certainly due to the large stresses upon the mechanisms involved in blood calcium regulation during a period of negative calcium balance. The hypocalcemia of calcium deprivation in humans is believed to be transient and very small changes in blood calcium concentration are considered to be corrected by bone mineral without the intervention of the parathyroid glands due to the existence of a genuine steady state between bone mineral and tissue fluid (Nordin *et al* 1965). However the results of the present study indicate that subnormal blood calcium values occur at different periods of time during prolonged calcium restriction and that these changes are relatively slowly corrected by bone mineral (see below). The falls in the blood calcium level recorded in the present investigation were further of such a magnitude that stimulated parathyroid activity might have been involved for the normalization of the blood calcium concentration.

Under normal circumstances the well documented constancy of blood calcium

After this initial phase there was a further rapid change in the distribution of Ca^{45} . Despite a continued subnormal blood calcium concentration there was a decrease to the normal level of the specific activity of Ca^{45} in the blood during the 3rd week of maintained calcium restriction. At the same time there was a shift to a corresponding increase by approximately 100 per cent in the deposition of Ca^{45} into bone mineral. The same distribution of Ca^{45} was observed during the 4th and 5th weeks of calcium restriction. These findings indicate indirectly that the subsequent normalization of blood calcium after the hypocalcemic period was brought about by increased bone resorption and mobilization of skeletal calcium to the blood. The observed increase in the deposition of Ca^{45} into bone mineral appears to be secondary to the still more augmented mobilization of bone calcium.

During the 5th week of calcium deficiency the blood calcium returned to normal and subsequently remained at a normal level until the 14th week. Initially in this period there was another shift in the distribution of Ca^{45} between blood and bone. Thus at the 8th week of calcium restriction the Ca^{45} activity of both blood and bone had reached a level 50 to 60 per cent above that of the normal controls. Thereafter this distribution of Ca^{45} remained unchanged until the 16th week.

These results clearly demonstrate a continued increased level of calcium retention during negative calcium balance induced by the maintained calcium restriction. In contrast the group of rats fed the test diet enriched with calcium showed significantly decreased Ca^{45} activity in both blood and bone in comparison with the normal controls. The fact that all animals received the same dose of Ca^{45} regardless of their body weight does influence the present results but only to quite a small extent. The higher final body weight of the experimental animals compared with the controls was due to an increase in adipose tissues in the former. With such an increase in adipose tissues the percentage total body water is reduced (Ljunggren *et al* 1957). This would imply that the experimental animals would have been afforded more Ca^{45} compared with that of the normal controls if the administered dose had been related to body weight. The results of the present study confirm earlier observations that animals accustomed to a high calcium intake must adjust their absorptive mechanism to a lower supply of calcium (Carlsson 1951; Hanard *et al* 1951; Nicolson *et al* 1953; Henry *et al* 1960). It must be pointed out that this situation is quite different from that when the intake of calcium is low throughout life. In these circumstances rats bred on a low calcium diet remain in calcium equilibrium at levels which would lead to negative calcium balance in rats

calcium intake is combined with various levels of dietary phosphorus. Changes in calcium metabolism and in the mechanisms involved in calcium homeostasis might then be expected in prolonged calcium restriction in aged humans also.

The described changes in the blood calcium level and the distribution of Ca^{45} between blood and bone 72 hours after the intraperitoneal administration of the isotope (Fig. 6) provide special interest, especially with regard to the development of osteoporosis. Thus the normal distribution of Ca^{45} rapidly changed upon restriction of the calcium intake. After only 1 week of calcium deficiency the rats showed an increase by approximately 100 per cent in the Ca^{45} specific activity in the blood and a slightly increased Ca^{45} activity in bone indicating increased calcium retention. This was probably the result of decreased endogenous Ca^{45} and to a minor degree decreased urinary Ca^{45} secondary to the observed fall in blood calcium. The adaptation of the rat to a reduced calcium intake is brought about by increased absorption of calcium and results in a decrease of the endogenous calcium (Nicolaysen *et al* 1953, Henry *et al* 1960). Also in humans adaptation to a reduced calcium intake is effected by a more efficient absorption (Malm 1958, Thorangkul *et al* 1959).

Fig. 6 For explanation see text above

in trabecular compared with cortical bone tissue. As for the whole tibia the Ca^{45} activity of the cortical bone powder in the present study was significantly higher for the long term calcium deficient rats than for the normal controls. In the 6 groups of rats fed the low calcium diet for 6 to 12 months the mean Ca^{45} uptake by the cortical bone was only 19 per cent higher while the mean uptake by the whole tibia was 41 per cent higher than in the normal controls. Contributory factors to these differences of 19 to 41 per cent might be the structural changes in cancellous bone described above and further the higher Ca^{45} activity of the bone marrow blood in the osteoporotic animals compared with the normal controls.

The Ca^{45} uptake by the small bones at different time intervals after the administration of the isotope showed a significant increase progressing with time after the isotope injection in the groups of rats maintained on prolonged calcium restriction while there was a slight tendency to a decrease in the normal control group. This difference could be explained by the consistent high Ca^{45} activity in the blood in the calcium deficient groups which would afford the bone more Ca^{45} to be built in compared with the normal controls.

In clinical osteoporosis the bone accretion rate or mineralization rate is usually reported to be normal (Heaney and Whedon 1958, Fraser et al 1960, Dow and Stanbury 1960, Dymling 1964, Nordin et al 1964) although both reduced accretion (Bauer et al 1957, Eisenberg and Gordon 1961, Dymling 1962, Bronner et al 1963, Lafferty et al 1964) and increased accretion (Nordin 1959) have also been observed. It was therefore considered of interest to estimate the calcium accretion rate in the osteoporotic animals of the present study. Estimations were performed on the whole tibia (mg calcium/hour/mg calcium of the tibia) of the rats of the long term series. In the group of rats maintained on a low calcium diet for 6 months a lower mean accretion rate was found than in the control group whereas in the groups kept on a restricted calcium intake for 7, 8, 9 and 10 months approximately the same values were found as in the normal control group. Finally the group of animals fed the low calcium diet for 12 months also showed a decreased accretion rate. In 4 month old rats fed a low calcium diet (calcium 0.037 per cent, phosphorus 0.45 per cent) for 6 months a normal accretion rate was found while the resorption was increased (Copp and Suiker 1962). These results are in agreement with those of the present study. However in the study of Copp and Suiker (1962) the effect of the treatment upon the skeletal tissue was not investigated further. The findings concerning the rate of calcium accretion in the present investigation indicate that the skeleton rendered osteoporotic by prolonged

bred on a higher or normal calcium diet (Henry and Kon 1953, Nicolaysen 1956) A similar adaptation is also well documented for humans (for ref see Henry and Kon 1953 Malm 1958)

With the continuation of the restricted calcium intake a slightly subnormal blood calcium was again observed in the rats kept on the low calcium diet for 16 weeks and 6 and 7 months At the 8th month of calcium restriction a normalization of the blood calcium concentration occurred and thereafter it remained normal until the 12th month A shift in the Ca^{45} distribution indicated that a new dynamic balance was induced in these animals by the prolonged calcium deficiency Thus, the Ca^{45} specific activity in blood showed an increase by 100 to 200 per cent while the Ca^{45} activity in bone was increased by only about 40 per cent In these animals the contribution of structural changes in cancellous bone to the balance and distribution of calcium must be considered With the development of osteoporosis there is a loss of cancellous bone and of cortical bone from the endosteal surfaces as described in the first part of the present investigation (Larsson 1969 a) The amount of bone surfaces available for negative calcium deposition i.e. surface accretion is reduced There was, further, no apparent change in the amount of bone surfaces showing new bone formation as observed with the tetracycline double labelling technique This demonstrates the importance of always considering these circumstances in dynamic calcium studies of normal and osteoporotic individuals Except for a change in the distribution of Ca^{45} between blood and bone due to the observed reduction of cancellous bone an accelerated calcium absorption i.e. a further decrease in endogenous Ca^{45} , as suggested by Nicolaysen *et al* (1963) and Henry *et al* (1960) would also contribute to the highly elevated Ca^{45} specific activity in blood observed in the osteoporotic rats By this regulation of the calcium distribution and by increased mobilization of bone calcium the blood calcium concentration can be sustained in prolonged negative calcium balance

The sequence of events reported here demonstrates that in induced negative calcium balance the efficiency of calcium homeostasis in maintaining extracellular fluid calcium is the primary pathomechanism for the development of calcium deficiency osteoporosis

The Ca^{45} activity of pooled cortical bone powder 72 hours after administration of the isotope was found to be less than $1/4$ of that of the whole tibia in the normal animals This relationship is of about the same order of magnitude as the corresponding ratio of tibia shaft to whole tibia found in normal young rats by Bauer and Carlsson (1955) It is well established that the calcium metabolism is more intensive in the ends than in the shaft of long bones and

in trabecular compared with cortical bone tissue. As for the whole tibia the Ca^{45} activity of the cortical bone powder in the present study was significantly higher for the long term calcium deficient rats than for the normal controls. In the 6 groups of rats fed the low calcium diet for 6 to 12 months the mean Ca^{45} uptake by the cortical bone was only 19 per cent higher while the mean uptake by the whole tibia was 41 per cent higher than in the normal controls. Contributory factors to these differences of 19 to 41 per cent might be the structural changes in cancellous bone described above and further the higher Ca^{45} activity of the bone marrow blood in the osteoporotic animals compared with the normal controls.

The Ca^{45} uptake by the small bones at different time intervals after the administration of the isotope showed a significant increase progressing with time after the isotope injection in the groups of rats maintained on prolonged calcium restriction while there was a slight tendency to a decrease in the normal control group. This difference could be explained by the consistent high Ca^{45} activity in the blood in the calcium deficient groups which would afford the bone more Ca^{45} to be built in compared with the normal controls.

In clinical osteoporosis the bone accretion rate or mineralization rate is usually reported to be normal (Heaney and Whedon 1958, Fraser et al 1960, Dow and Stanbury 1960, Dymling 1964, Nordin et al 1964) although both reduced accretion (Bauer et al 1957, Eisenberg and Gordan 1961, Dymling 1962, Bronner et al 1963, Lafferty et al 1964) and increased accretion (Nordin 1959) have also been observed. It was therefore considered of interest to estimate the calcium accretion rate in the osteoporotic animals of the present study. Estimations were performed on the whole tibia (mg calcium/hour/mg calcium of the tibia) of the rats of the long term series. In the group of rats maintained on a low calcium diet for 6 months a lower mean accretion rate was found than in the control group whereas in the groups kept on a restricted calcium intake for 7, 8, 9 and 10 months approximately the same values were found as in the normal control group. Finally the group of animals fed the low calcium diet for 12 months also showed a decreased accretion rate. In 4 month old rats fed a low calcium diet (calcium 0.037 per cent, phosphorus 0.45 per cent) for 6 months a normal accretion rate was found while the resorption was increased (Copp and Suiker 1962). These results are in agreement with those of the present study. However in the study of Copp and Suiker (1962) the effect of the treatment upon the skeletal tissue was not investigated further. The findings concerning the rate of calcium accretion in the present investigation indicate that the skeleton rendered osteoporotic by prolonged

calcium restriction retains calcium to approximately the same extent as the normal skeleton, although a reduced accretion was found in some groups of rats. These results are in good agreement with those generally reported for human osteoporosis. However, when the rate of calcium accretion by bone in osteoporotic individuals is compared with that in normals, differences in bone mass must be considered. Furthermore, the higher Ca^{45} activity in the bone marrow blood of the osteoporotic animals in the present study compared with that of the normal controls will also influence the obtained values. It must be pointed out moreover that bone accretion cannot be equated with bone formation which has been done in many earlier studies. In the present investigation calcium accretion is interpreted as a measure only of the retention of calcium by the whole bone and not of the formation of new bone. In a previous study (Larsson 1969 a), no appreciable difference from the normal was found in the amount of bone surfaces showing new bone formation as estimated by the tetracycline labelling method. Normal female rats of the same strain and age as the normal male rats of the present study showed a lower frequency of tetracycline labelled surfaces of the vertebral bone (Larsson 1969 b) and also a lower bone Ca^{45} retention (Larsson 1969 c). These findings might indicate some relationship between accretion and bone formation. Nevertheless it is well known that the amount of tracer localized as diffuse uptake in the bone tissue is both high and variable and this usually makes such a correlation difficult to establish (Rowland 1960).

In the pathogenesis of generalized osteoporosis in humans a low intake or malabsorption of calcium has been considered to play an important role (Norain 1960, 1961, 1962, 1964) as well as the efficiency of calcium homeostasis (Heaney 1965). After the institution of a low calcium diet in human volunteers a negative calcium balance has been observed for relatively long periods of time (Malm 1958). However, there is no evidence to prove that calcium deficiency really gives rise to osteoporosis in humans. The adaptation to a low calcium intake has been studied extensively in old rats by calcium balance techniques (Henry and Kon 1947, 1953; Baruch and McCay 1954; Nicolaysen 1943, 1955; Henry *et al.* 1960). In humans principally the same adaptory mechanisms are responsible as in the rat (Nicolaysen *et al.* 1953). In a previous investigation (Larsson 1969 a) the development of osteoporosis was observed in old rats after prolonged calcium restriction. The findings presented here show that significant changes in the calcium dynamics occur during this process of bone reduction. It is suggested that this course of events proceeds in different phases in the adaptation to a low calcium intake. Initially and also later the

blood calcium level is subnormal due to the low calcium intake. Because of the efficiency of calcium homeostasis the blood calcium level is normalized. The Ca^{45} data presented here indicate indirectly that this normalization of the blood calcium level is brought about by increased bone resorption mobilizing skeletal calcium to the blood at the expense of the bone mass.

SUMMARY

One year old fully grown rats were maintained on a low calcium diet with normal contents of phosphorus and vitamin D for periods varying from 1 week up to 1 year. Seventy two hours before sacrifice 20 microcuries of Ca^{45} were administered to each animal by intraperitoneal injection and the Ca^{45} activity in plasma and bone was compared with that of normal controls and in addition with that of animals fed the test diet enriched with calcium.

The plasma Ca^{45} activity 72 hours after the isotope injection showed increased values by 100 per cent in the group of rats fed the low calcium diet for 1 week when compared with that of the normal controls. The groups of animals kept on a restricted calcium intake for 3 and 4 weeks showed the same values as the controls. In these experimental groups there was a significant increase by 100 per cent in the deposition of Ca^{45} into the skeleton while there was a concomitant slight fall in the plasma calcium. In the groups of rats fed the low calcium diet for 8 to 14 weeks the plasma calcium was normal and in these groups there was an increase in the plasma and bone Ca^{45} activity by 50 to 60 per cent. In the groups of animals kept on the low calcium intake for 4 to 7 months the plasma calcium was again slightly reduced. These groups and those treated for 9 to 12 months showed an increase in the plasma Ca^{45} activity by 100 to 200 per cent whereas the Ca^{45} activity in bone was increased by 40 per cent. The groups treated for 8 to 12 months showed normalized plasma calcium. In the group of rats fed the diet enriched with calcium the plasma Ca^{45} activity was 40 per cent lower and the bone Ca^{45} activity 60 per cent lower than in the control group. The plasma calcium showed normal values.

The calculated calcium accretion rate for the tibia (mg calcium/hour/mg calcium of the tibia) was described in rats fed the low calcium diet for 6 and

calcium restriction retains calcium to approximately the same extent as the normal skeleton although a reduced accretion was found in some groups of rats. These results are in good agreement with those generally reported for human osteoporosis. However, when the rate of calcium accretion by bone in osteoporotic individuals is compared with that in normals differences in bone mass must be considered. Furthermore the higher Ca^{45} activity in the bone marrow blood of the osteoporotic animals in the present study compared with that of the normal controls will also influence the obtained values. It must be pointed out moreover that bone accretion cannot be equated with bone formation which has been done in many earlier studies. In the present investigation calcium accretion is interpreted as a measure only of the retention of calcium by the whole bone and not of the formation of new bone. In a previous study (Larsson 1969 a) no appreciable difference from the normal was found in the amount of bone surfaces showing new bone formation as estimated by the tetracycline labelling method. Normal female rats of the same strain and age as the normal male rats of the present study showed a lower frequency of tetracycline labelled surfaces of the vertebral bone (Larsson 1969 b) and also a lower bone Ca^{45} retention (Larsson 1969 c). These findings might indicate some relationship between accretion and bone formation. Nevertheless it is well known that the amount of tracer localized as diffuse uptake in the bone tissue is both high and variable and this usually makes such a correlation difficult to establish (Rowland 1960).

In the pathogenesis of generalized osteoporosis in humans a low intake or malabsorption of calcium has been considered to play an important role (Nordin 1960 1961 1962 1964) as well as the efficiency of calcium homeostasis (Heaney 1965). After the institution of a low calcium diet in human volunteers a negative calcium balance has been observed for relatively long periods of time (Malm 1958). However there is no evidence to prove that calcium deficiency really gives rise to osteoporosis in humans. The adaptation to a low calcium intake has been studied extensively in old rats by calcium balance technique (Henry and Kon 1947 1953 Barucha and McCay 1954 Nicolaysen 1943 1955 Henry et al 1960). In humans principally the same adaptory mechanisms are responsible as in the rat (Nicolaysen et al 1953). In a previous investigation (Larsson 1969 a) the development of osteoporosis was observed in old rats after prolonged calcium restriction. The findings presented here show that significant changes in the calcium dynamics occur during this process of bone reduction. It is suggested that this course of events proceeds in different phases in the adaptation to a low calcium intake. Initially and also later the

blood calcium level is subnormal due to the low calcium intake. Because of the efficiency of calcium homeostasis the blood calcium level is normalized. The Ca^{45} data presented here indicate indirectly that this normalization of the blood calcium level is brought about by increased bone resorption mobilizing skeletal calcium to the blood at the expense of the bone mass.

SUMMARY

One year old fully grown rats were maintained on a low calcium diet with normal contents of phosphorus and vitamin D for periods varying from 1 week up to 1 year. Seventy two hours before sacrifice 20 microcuries of Ca^{45} were administered to each animal by intraperitoneal injection and the Ca^{45} activity in plasma and bone was compared with that of normal controls and in addition with that of animals fed the test diet enriched with calcium.

The plasma Ca^{45} activity 72 hours after the isotope injection showed increased values by 100 per cent in the group of rats fed the low calcium diet for 1 week when compared with that of the normal controls. The groups of animals kept on a restricted calcium intake for 3 and 4 weeks showed the same values as the controls. In these experimental groups there was a significant increase by 100 per cent in the deposition of Ca^{45} into the skeleton while there was a concomitant slight fall in the plasma calcium. In the groups of rats fed the low calcium diet for 8 to 14 weeks the plasma calcium was normal and in these groups there was an increase in the plasma and bone Ca^{45} activity by 50 to 60 per cent. In the groups of animals kept on the low calcium intake for 4 to 7 months the plasma calcium was again slightly reduced. These groups and those treated for 9 to 12 months showed an increase in the plasma Ca^{45} activity by 100 to 200 per cent whereas the Ca^{45} activity in bone was increased by 40 per cent. The groups treated for 8 to 12 months showed normalized plasma calcium. In the group of rats fed the diet enriched with calcium the plasma Ca^{45} activity was 40 per cent lower and the bone Ca^{45} activity 60 per cent lower than in the control group. The plasma calcium showed normal values.

The calculated calcium accretion rate for the tibia (mg calcium/hour/mg calcium of the tibia) was described in rats fed the low calcium diet for 6 and

12 months, while in rats treated for 7 8 9 and 10 months the values were approximately the same as in the control group

The results show that a slight initial fall in plasma calcium occurs on instituting a low calcium diet to adult rats, and also at later stages subnormal plasma calcium values can be observed. The findings concerning Ca^{45} indicate indirectly that the normalization of plasma calcium is brought about by increased mobilization of skeletal calcium to the blood. This results in a reduction of bone mass and the development of osteoporosis.

treatment results after 100 days in radiographically evident osteoporosis Oestradiol cures the osteoporosis in these animals despite continuous cortisone administration while only very slight improvement occurs in rats given testosterone (Caldwell 1962) The curative effect of oestrogens has also been observed in birds rendered severely osteoporotic with large doses of ACTH or cortisone (Urist 1958) In young rats but not in other animals oestrogens inhibit bone resorption (Budy et al 1952 Lindquist et al 1960)

The inhibitory effect of excess cortisone upon normal skeletal growth is well known In the experiments performed on rabbits young growing animals were used and in addition to the osteoporotic changes inhibited bone growth was observed (Sissons and Hadfield 1955 Storey 1957 deValderrama and Munuera 1965) This inhibitory effect is also well documented for young rats (Follis 1951 Laron et al 1958 Kowalewski 1962 Stanisavljevic et al 1952 Hulth and Olerud 1963 Tapp 1966) As far as the young growing animal is concerned both interference with normal skeletal growth and a possible eventual effect on the calcium metabolism must be taken into consideration In view of the inhibitory effect of cortisone on the formation of connective tissues (Asboe-Hansen 1961) inhibited synthesis of bone matrix is furthermore to be expected

The present investigation was undertaken in order to examine the effect of combined oophorectomy and prednisolone administration on the mature skeleton of one year old fully grown rats and to study the eventual development of skeletal changes during the progress of treatment The aim of this study was to determine whether this hormonal disturbance does in fact give rise to bone reduction of the mature skeleton of the adult rat as might be expected from the results concerning growing rats in the experiments of Caldwell (1962)

EXPERIMENTAL

Animals

A total of 55 adult female rats of the Sprague Dawley strain¹ were used All animals were stated to be 11 ± 1 to 12 months old at the start of the experiment and their mean initial body weight was 348.5 ± 2.7 grams The animals were divided at random into ten experimental groups and one control group of 5

INTRODUCTION

The hypothesis that oestrogen deficiency is the cause of human osteoporosis was advanced by *Albright and Reifenstein* (1948). This hypothesis was modified to include the possibility that senile as well as other forms of osteoporosis are caused by a state of lack of balance between anabolic or gonadal hormones and anti-anabolic or adrenal corticoid hormones (*Reifenstein* 1957). Hypercorticism of endogenous origin in humans is often associated with osteoporosis (*Follis* 1951). Osteoporosis is moreover one of the most serious complications in prolonged cortisone therapy (*Bunim et al* 1955, *Rosenberg* 1958).

Osteoporosis has been induced experimentally in young rabbits by cortisone administration (*Sissons and Hadfield* 1955, *Storey* 1957). *Sissons* (1956) pointed out the similarity of these lesions to those observed in Cushing's disease. As far as the rabbit is concerned it has been concluded that the effect of cortisone is inhibitory to new bone formation and that bone rarefaction is due to the unopposed continuance of the normal osteolytic processes (*Sissons and Hadfield* 1955, *Sissons* 1956). From histological observations it has also been deduced that cortisone osteoporosis results not only from a cessation of bone formation but primarily from a direct degrading effect which causes a massive resorption of bone (*deValderrama and Munuera* 1965).

Unlike the rabbit the young growing rat does not always develop osteoporosis after cortisone administration. Instead dense metaphyseal bone has been observed. This was believed to be due to delayed bone resorption (*Follis* 1951). However when the dietary Ca and P are lowered or the ratio altered during cortisone administration also young rats develop osteoporosis similar to that seen in rabbits treated with cortisone. In cortisone treated rats maintained on a diet containing 1.5 per cent Ca and 1.0 per cent P increased density of the metaphyseal bone occurs. At a normal Ca/P level i.e. 1.0 per cent Ca and 0.6 per cent P or a reduced level osteoporosis develops. This difference in the reaction of the bone has been believed to be associated with the well developed adaptive calcium metabolism of 30-day rats (*Storey* 1960).

Growing male rats subjected to bilateral adrenalectomy and orchidectomy become more sensitive to cortisone. In spite of a high calcium intake cortisone

treatment results after 100 days in radiographically evident osteoporosis. Oestradiol cures the osteoporosis in these animals despite continuous cortisone administration while only very slight improvement occurs in rats given testosterone (Caldwell 1962). The curative effect of oestrogens has also been observed in birds rendered severely osteoporotic with large doses of ACTH or cortisone (Urist 1958). In young rats but not in other animals oestrogens inhibit bone resorption (Budy et al 1952, Lindquist et al 1960).

The inhibitory effect of excess cortisone upon normal skeletal growth is well known. In the experiments performed on rabbits young growing animals were used and in addition to the osteoporotic changes inhibited bone growth was observed (Sissons and Hadfield 1955, Storey 1957, deValderrama and Munuera 1965). This inhibitory effect is also well documented for young rats (Follis 1951, Laron et al 1958, Kowalewski 1962, Stanisavljevic et al 1962, Hulth and Olerud 1963, Tapp 1966). As far as the young growing animal is concerned both interference with normal skeletal growth and a possible eventual effect on the calcium metabolism must be taken into consideration. In view of the inhibitory effect of cortisone on the formation of connective tissues (Asboe-Hansen 1961) inhibited synthesis of bone matrix is furthermore to be expected.

The present investigation was undertaken in order to examine the effect of combined oophorectomy and prednisolone administration on the mature skeleton of one year old fully grown rats and to study the eventual development of skeletal changes during the progress of treatment. The aim of this study was to determine whether this hormonal disturbance does in fact give rise to bone reduction of the mature skeleton of the adult rat as might be expected from the results concerning growing rats in the experiments of Caldwell (1962).

EXPERIMENTAL

Animals

A total of 55 adult female rats of the Sprague Dawley strain¹ were used. All animals were stated to be 11¹/₂ to 1² months old at the start of the experiment and their mean initial body weight was 348.5 ± 2.7 grams. The animals were divided at random into ten experimental groups and one control group of 5

¹Intrex Co. Stockholm, Sweden

rats each. The experimental animals were oophorectomized under ether anaesthesia via a midline abdominal incision under sterile conditions. The identification of the first ovaries removed was verified by histological examination. All the animals recovered very quickly after the operation. No postoperative complications were observed. From the third day after oophorectomy each animal received 2.5 mg prednisolone¹ daily dissolved in their drinking water which was supplied intermittently in such a way that the prednisolone was consumed within 1–2 hours. The periods of prednisolone treatment varied from 1 to 16 weeks. The control group consisted of normal rats and was observed for 16 weeks. These animals were not oophorectomized and received no prednisolone but were otherwise treated in the same way as the experimental animals.

The animals were housed individually in screen bottomed wire cages in a separate room without access to direct sunlight and with a room temperature of 18–20°C. All animals received the same laboratory ration and tap water in unrestricted quantities except for the intermittent supply of drinking water in the experimental animals during administration of prednisolone, as mentioned above. Chemical analysis of the diet given showed that it contained a total of 1.0 per cent calcium and 0.55 per cent phosphorus. The quantity of food consumed was estimated for one animal of each group during a period of 5 days starting at the 7th day before sacrifice by recording daily the weight of the pellets given to each animal and the weight of the food not consumed. No antibiotics were given. The series were planned so that all the animals were sacrificed at the same time. This was performed by bleeding them to death from the femoral artery under ether anaesthesia.

Methods

The methods used are essentially the same as described in greater detail in a previous paper (Larsson 1969 a).

Body weight and weight of the adrenals

All the animals were weighed weekly. From all animals the adrenal glands were removed after sacrifice. The glands were dissected free from all surrounding fat tissue; they were immediately placed in weighing containers and their wet weight was recorded on a Mettler balance with an accuracy of 0.05 mg.

¹ Precortalon Aquosum[®] kindly supplied by Pharmacia Ltd Uppsala Sweden
Ewos Co. Södertälje Sweden

Radiography

The skeleton of each animal was examined radiographically under light ether anaesthesia at the beginning and end of the experimental period. Each rat was placed with the spinal column and the extremities fixed directly on an X-ray film. The same exposure conditions, film and developer were used throughout.

Measurement of the cortical thickness of the mid shaft of the femur

This was performed after division of the bone at the middle of the diaphysis (± 0.5 mm) perpendicular to its long axis. The internal and external transverse diameters were carefully measured with the aid of a vernier caliper at the four cut surfaces of the two divided femora of each animal. Mean values were used. The cortical thickness at this point was calculated as the difference between the external and the internal diameter and with an accuracy of 0.05 mm. This figure was divided by the value for the external transverse diameter of the shaft at the same level and this fraction was multiplied by 100. In this way the femoral score was calculated according to *Barnett and Jordan (1960)*.

Ash determinations

The ash content of the whole right tibia including the bone marrow and articular cartilages was determined as described previously (*Larsson 1969 a*) and was expressed as per cent of the wet weight.

Hydroxyproline determinations

The hydroxyproline content of the whole third metacarpal bone including the bone marrow and the articular cartilages was determined by the method of *Newman and Logan (1950)*. All bones within the whole series were dried simultaneously at 45 C for 74 hours and were then weighed in weighing containers. Protein hydrolysates were prepared by autoclaving the whole bone with 0.5 ml of 6 N hydrochloric acid in sealed tubes for 10 hours at 100 C. Duplicate determinations were performed throughout and the mean value was used. The coefficient of variation for these analyses was 2.0 per cent.

Density of the dried humerus

The density of the dried whole bone including the bone marrow and articular cartilages was determined according to the method of *Robinson and Elliott (1957)*.

Preparation of undecalcified sections

The first tail vertebra of all the rats was freed of most of the surrounding soft tissues and then fixed and dehydrated in 6 changes of 96 per cent alcohol for 6 days. The specimens were embedded in methacrylate as described earlier (Larsson 1969 a). Using a fine bandsaw the trimmed plastic blocks were cut into sections approximately 0.5 mm thick and exactly perpendicularly to the long axis of the vertebra.

Quantitation of the amount of vertebral bone

Quantitative determination of bone present in a standard area was performed as follows. Undecalcified methacrylate embedded sections from the first tail vertebra were ground first on an oscillating grinder and then by hand to a thickness of approximately $50\ \mu$. Only that section which contained most of the transverse processes was examined unstained with the aid of an integrating eyepiece (Zeiss I) as described by Wagner (1965). The number of vertebral bone hits of 200 points was determined with the point network exactly in the centre of the section at a linear magnification of $30\times$.

Microradiography

Of all the animals undecalcified methacrylate embedded cross sections from the second tail vertebra were ground on a Knuth Rotor grinder to a thickness of approximately $90\ \mu$ with water as a lubricant and using Silicone Carbide papers Nos 220 and 600. The sections were radiographed on Kodak MR plates in a Philips PW 1009 apparatus. The procedure was the same as described previously (Larsson 1969 a).

Tetracycline labelling

All animals were labelled with chlortetracycline (Aureomycin[®] Lederle) in 2 doses of 20 mg per kg body weight administered by intraperitoneal injection 10 and 20 days before sacrifice. Approximately $60\ \mu$ thick undecalcified methacrylate embedded cross sections from the second tail vertebra were mounted under coverslips in fluorescence free balsam (Permount) and were examined in a fluorescence microscope (Zeiss) fitted with an UV High Pressure Vacuum lamp HBO 200 with exciter filters UG 2 and UG 5 and barrier filters 65 and 41.

Preparation of decalcified sections

The third tail vertebra of all animals was fixed in 10 per cent neutral formalin for 24 hours and then decalcified for 12—14 days in a mixture of equal parts of 20% monosodium citrate and 44% formic acid. The specimens were then immersed in 5 per cent disodium sulphate for 24 hours, washed with water for 24 hours and dehydrated by successive immersion in 70 per cent, 95 per cent and absolute alcohol (2 changes). The specimens were then immersed first in methyl benzoate and then in xylol and were finally embedded in paraffin. Sections 5 μ thick were cut and were stained with Ehrlich's haematoxylin and eosin and in addition azocarmine G. Adjacent sections were also stained with an 0.5 per cent solution of toluidine blue in phthalate at pH 4.4 as described by Belanger and Hartnett (1960).

Preparation of histological sections of the adrenals

The adrenal glands from the normal controls and the animals treated for 14 and 16 weeks were fixed in 10 per cent neutral formalin, embedded in paraffin and cut into sections 5 μ thick. Representative sections were stained with Ehrlich's haematoxylin and eosin.

Statistical treatment of data

The analytical data obtained from the rats in each group were subjected to analysis of variance with one way lay out according to Scheffe (1961). The hypothesis of no difference between groups was tested at the 5 per cent significance level. When a significant result was obtained, data of one or more groups were combined in order to find significant contrasts. These were tested according to Scheffe (1961). In the present study the term significant stands for statistically significant as found with the tests described above.

RESULTS

All animals survived the treatment except one. This animal was sacrificed because of a parotid tumour and was excluded. No infections or any other intercurrent diseases occurred. The normal control animals showed a slight increase in body weight by 5 to 7 per cent during the first 6 weeks. Subsequently

Table 1.2. The initial and final body weights of normal control rats and oophorectomized rats treated with prednisolone for different periods of time (S.E.M. = standard error of the mean)

until the end of the 16th week the body weight remained unchanged. All the experimental animals showed a considerable loss of body weight (Table 1 a, b Fig. 1). During the first 3 weeks of prednisolone treatment there was a decrease in body weight by approximately 20 per cent, after which there was a further decrease by 10 per cent of the initial value. The estimated food consumption was found to be slightly less than normal during the first 2 weeks of prednisolone treatment. Subsequently there was no appreciable change in food intake in relation to body weight. Considerable depletion of the adipose and muscle tissues and atrophy of the skin occurred in all corticosteroid treated animals. Otherwise the animals were in good health and moved about freely in their cages.

Table 1 b. The percent change in body weight of the initial value in normal controls and oophorectomized rats treated with prednisolone for 16 weeks.

Fig 1 Body weight change in per cent of the initial weight in normal control rats (whole line) and in oophorectomized rats treated with prednisolone for 16 weeks (broken line) The bars represent the standard error of the mean

The length of the femur showed no significant difference between the normal control group and the groups of oophorectomized rats treated with prednisolone for 1 to 16 weeks

Histological examination of the ovaries removed from ten animals revealed both primary and secondary follicles in all specimens

Radiography

The radiograms of the skeleton showed closed epiphyseal zones in all animals at the start of the experimental period. On comparison of the radiograms obtained at the start and at the end of the experimental period no noteworthy changes in the calcification of the skeleton were observed in any of the animals

Cortic 1 thickness at the mid shaft of the femur (Table 2)

In the ten groups of oophorectomized rats treated with prednisolone for 1 to 16 weeks consistently lower mean values were found when compared with that of the normal control group. In the groups treated for 8 and 16 weeks respectively the calculated femur score was significantly lower than that of the control group. The mean values of the nine groups of rats treated for 2 to 16 weeks were approximately 10 to 20 per cent lower than that of the control group.

Microradiography

The microradiographs of undecalcified vertebral cross sections from the animals in the control group showed that both the cortical and the trabecular bone were evenly mineralized (Fig. 2). In this nonlamellar (woven) bone there were no secondary osteones and no resorption cavities. In all experimental animals microradiography showed that the cortical and the trabecular bone had the

Fig. 2. Micrograph of a cross section through the second tail vertebra of a normal rat. (x25)

same degree of mineralization and were as evenly mineralized as in the control animals. In the experimental animals the bone trabeculae appeared slightly thinner than in the normal controls but otherwise no differences were found (Fig. 3). No resorption cavities were seen.

Histological observations

In all animals decalcified cross sections of the third tail vertebra were stained with toluidine blue at pH 4.4 and in addition with haematoxylin eosin and azocarmine C. The sections were cut from parts of the vertebra chosen at random in the different animals. In each animal however all the sections were

Fig. 3 Microradiograph of a cross section through a corresponding part of the second tail vertebra of a rat after combined oophorectomy and prednisolone administration for 16 weeks. The bone trabeculae are slightly thinner than normal (x25).

cut from the same part of the vertebra allowing adjacent sections to be examined after the three different staining procedures.

In both the cortical and the trabecular bone of the normal animals osteocytes with enlarged almost spherical lacunae were frequently found. These osteocytes had often retracted to the lacunar wall and showed a pyknotic nucleus (Fig. 4). Lacunae which were empty of cells were regularly found especially in the cortical bone mid way between the marrow cavity and the periosteum but often in the cortical bone layers nearest to the cavity and also in the bone trabeculae. These lacunae and the canaliculi stained violet with haematoxylin eosin and were metachromatic with toluidine blue. The immediate border of the osteocyte lacunae and the canaliculi stained violet with haematoxylin eosin and were metachromatic with toluidine blue. This was often found also in lacunae empty of cells. No osteoid tissue was observed nor osteoblasts or osteoclasts.

Distinct areas showing slight basophilic staining with haematoxylin eosin were regularly found in the trabecular bone of the metaphyseal parts of the vertebra (Fig. 5). Nearer the midportion of the vertebra the basophilic areas decreased in frequency and were not seen in the cortical bone. They stained only faintly blue with azoarmine G and were located in the spaces intervening between parallel fibered bone staining deep blue (Fig. 6). These areas showing basophilic staining with haematoxylin eosin gave evident metachromasia with toluidine blue (Fig. 7).

In the experimental animals the same histological observations were made as in the normal controls. The osteocytes, the lacunae, the capsule of the lacunae and the canaliculi had the same appearance and showed the same staining properties in the prednisolone treated oophorectomized animals as in the controls. No difference in the frequency of hypertrophic osteocyte and lacunae empty of cells was observed. Neither were osteoid tissue, osteoblasts or osteoclasts

Weight and histology of the adrenals (Table 7)

All the ten groups of oophorectomized rats treated with prednisolone for 1 to 16 weeks showed a decrease in the weight of the adrenals. In the five groups of rats treated for 8 to 16 weeks the decrease was significant. This also held when the weight of the adrenals was correlated to the body weight.

Histological examination showed pronounced atrophy of the zona fasciculata in the corticosteroid treated animals.

DISCUSSION

This study is concerned with the reaction of the well mineralized skeleton of one year old fully grown female rats to combined oophorectomy and prednisolone treatment for different periods of time. It has been observed earlier that after

Fig. 11 Fluorophotomicrograph of undecalcified section of vertebral bone from a normal rat. Despite the time interval of 10 days between the 2 administered doses of chlortetracycline only one narrow fluorescent line can be seen ($\times 400$)

observed in the treated animals. The areas showing metachromasia with toluidine blue exhibited the same staining properties in corticosteroid treated as in normal animals (Figs 8—10).

Fluorescence microscopy

In the normal animals fluorescence of newly formed bone was observed in only very few parts of the trabecular bone surfaces and on the surfaces of bone canals (Fig. 11). Despite the time interval of 10 days between the two administered doses only one narrow fluorescent line was found. These observations indicate that the rate of new bone formation in these old rats is very low. In the experimental animals the fluorescent micrographs (Fig. 12) were similar to those in the normal controls.

Table 7 Weight of the adrenals (m_g) and weight of the adrenals/body weight ($\times 10^{-3}$) in normal control rats and in oophorectomized rats treated with prednisolone for different periods of time

a certain age female rats attain a constant body weight (Singer *et al* 1952) This was found also in the present study in which the body weight of the normal control rats remained unchanged after about the 6th week of the experiment The radiological examination showed further that the skeletal growth was complete in all animals at the beginning of the experiment No significant difference in femur length was found between normal and experimental animals

In the present study oophorectomy was performed in order to reduce the endogenous oestrogens which are known to have a calcium retaining effect in contradistinction to the calcium wasting effect of corticosteroids (Gordan *et al* 1967) In addition to considerable depletion of adipose and muscle tissues and atrophy of the skin the effect of the treatment was manifested by pronounced atrophy of the adrenal cortex especially the zona fasciculata Rats treated with cortisone for 21 days show a selective depletion of lipid in the zona fasciculata and the zona reticularis whereas the zona glomerulosa becomes hypertrophied and full of lipid (Wexler 1963) This inactivity of the adrenal cortex induced by cortisone administration would mean a decrease not only of endogenous cortisone from the zona fasciculata but also of oestrogens and androgens from the zona reticularis Furthermore histological examination of the ovaries removed in the present experiment revealed both primary and secondary follicles These circumstances indicate that the experimental conditions of the present study induced the hormonal lack of balance which has been considered to cause senile osteoporosis in humans (Reifenstein 1957)

In an earlier experiment designed to study the effect on the skeleton of a hormonal disturbance similar to that in osteoporotic humans as reported by Reifenstein (1957) young male rats were deprived of endogenous adrenal corticosteroid and gonadal steroid hormones by total adrenalectomy and gonadectomy and were injected daily with cortisone acetate in a dose of 7 mg per kg body weight (Caldwell 1962) There was radiographic evidence of osteoporosis after 100 days of cortisone treatment and after 160 days the ratio femoral calcium/wet weight showed a decrease by approximately 25 per cent In the adult oophorectomized rats studied in the present investigation no radiographic signs of osteoporosis were observed at any period of the prednisolone treatment The ash content of the whole tibia showed a slight decrease initially but no consistent change was observed subsequently in the rats treated for different periods of up to 12 weeks Thereafter a significant decrease by 6 to 7 per cent was noted in the two groups of rats treated for 14 and 16 weeks respectively Histological examination of decalcified sections and microradiographs of undecalcified vertebral sections showed no differences from the normal The

loss of bone minerals observed in the rats treated for 14 and 16 weeks therefore corresponds to osteoporosis as described by Collins (1966). This is supported by the fact that in a subsequent study (Larsson and Vejlens 1969) on the same material no significant change in the ash content of the compact bone was found in these animals. The tendency to a decrease of the hydroxyproline content of the whole metacarpal bone observed in the present study also suggests a reduction of skeletal tissue. The same tendency to slightly decreased values was found with regard to the cortical thickness of the mid shaft of the femur, the percentage of vertebral bone hits and the density of the whole humerus. Except for the femur score no significant differences were found with these methods which might have been due to greater methodological variations than for the ash determinations.

In view of the considerable depletion of other tissues such as adipose and muscle tissues and the skin the skeletal tissue of the adult rat must be regarded as fairly stable to the action of combined oophorectomy and excess corticosteroids. From results obtained in adult rats after cortisone treatment alone for up to 8 weeks the same conclusion concerning bone collagen was reached by Sobel and Marmorston (1954). These findings are in contradistinction to results concerning the young growing skeleton of the rat (Storey 1960, Caldwell 1962) and of the rabbit (Sissons and Hadfield 1957, Storey 1957, deValderrama and Munuera 1965). In rabbits also the effect of corticosteroids on the adult skeleton is less pronounced than in young animals (Storey 1961).

It seems as if the hormonal disturbance induced in the experiment of Caldwell (1962) had a more pronounced effect on the skeletal tissue than that of the present study. However in Caldwell's experiment young growing rats were used and the results of the two studies are therefore not comparable. Thus combined adrenalectomy, orchidectomy and cortisone treatment caused a pronounced interference with the normal skeletal growth and development. Also in other experimental studies where young animals have been used the reported osteoporotic bone lesions induced by excess corticosteroids seem to have been mainly the result of interference with normal skeletal development. In the present investigation on fully grown animals the hormonal disturbance exerted its effect on the maintenance of the mature skeletal tissue which is the essential problem in connection with the development of osteoporosis in humans.

It has been proposed that senile osteoporosis develops as a result of inhibited protein synthesis of the bone matrix (Reisenstein 1957). There is experimental evidence that cortisone primarily reduces the synthesis of bone collagen and does not increase its degradation in the rat (Smith and Allison 1965). Results

obtained in studies of the metabolism of bone collagen following intraperitoneal injection of glycine 2 C¹⁴ in the rat indicate that a major proportion of bone collagen is synthesized at an early age and that the rate of metabolism of collagen in bone is an inverse function of age (Hao et al 1965). This means that the reaction of bone collagen to excess cortisone is more pronounced in young than in adult individuals. Besides this inhibitory effect upon collagen synthesis the well documented calcium wasting effect of corticosteroids (Gordan et al 1967) may also be more pronounced in the growing skeleton not only because of the high rates of bone apposition and resorption in the young animal but also because of more extensive bone calcium exchange in the young than in the mature skeleton (Leblond et al 1950 Tomlin et al 1953). In humans adrenal steroids have been reported to produce osteoporotic bone lesions in children more frequently than in adults and generally after treatment on lower doses and in less time (Schlesinger et al 1961).

It has been found in experiments on young growing rats that calcium intake and changes in calcium metabolism may be of primary importance for the development of osteoporosis following corticosteroid therapy (Storey 1960). Young rabbits treated with cortisone and fed a low calcium diet develop osteoporosis associated with extensive osteoclastic activity and secondary hyperthyroidism (Storey 1961). The experiment of Clark and Roth (1961) suggests that hydrocortisone decreases the reabsorption of calcium by the renal tubules in the adult rat. This calcium wasting effect was also demonstrated in a study on the same material as used in the present experiment (Larsson 1969 b). The data obtained indicated increased mobilization of skeletal calcium for maintenance of the blood calcium level. There was no consistent change in the calcium accretion rate of the bone. The decrease in bone mass found in the present study therefore represents a considerable calcium loss and corresponds well with that observed in one year old male rats fed a low calcium diet (0.09 per cent calcium) for the same periods of time (Larsson 1969 a). In that experiment also a significant reduction of the ash content of the whole tibia by 6 to 7 per cent was noted after 14 and 16 weeks on a low calcium diet. These findings suggest that changes in calcium metabolism and the efficiency of calcium homeostasis may be of major importance for the slight bone mass reduction observed after combined oophorectomy and prednisolone administration in the present study. It is possible that a more significant reduction in bone mass might occur on extension of the duration of prednisolone treatment. However it is conceivable that reduction in caloric intake might then occur and this alone can give rise to osteoporosis (El Maraghi et al 1965). In the present

loss of bone minerals observed in the rats treated for 14 and 16 weeks therefore corresponds to osteoporosis as described by *Collins* (1966). This is supported by the fact that in a subsequent study (*Larsson and Vejlens* 1969) on the same material no significant change in the ash content of the compact bone was found in these animals. The tendency to a decrease of the hydroxyproline content of the whole metacarpal bone observed in the present study also suggests a reduction of skeletal tissue. The same tendency to slightly decreased values was found with regard to the cortical thickness of the mid shaft of the femur, the percentage of vertebral bone hits and the density of the whole humerus. Except for the femur score no significant differences were found with these methods which might have been due to greater methodological variations than for the ash determinations.

In view of the considerable depletion of other tissues, such as adipose and muscle tissues and the skin, the skeletal tissue of the adult rat must be regarded as fairly stable to the action of combined oophorectomy and excess corticosteroids. From results obtained in adult rats after cortisone treatment alone for up to 8 weeks the same conclusion concerning bone collagen was reached by *Sobel and Marmorston* (1954). These findings are in contradistinction to results concerning the young growing skeleton of the rat (*Storey* 1960, *Caldwell* 1962) and of the rabbit (*Sissons and Hadfield* 1957, *Storey* 1957, *deValderrama and Munuera* 1965). In rabbits also the effect of corticosteroids on the adult skeleton is less pronounced than in young animals (*Storey* 1961).

It seems as if the hormonal disturbance induced in the experiment of *Caldwell* (1962) had a more pronounced effect on the skeletal tissue than that of the present study. However in *Caldwell's* experiment young growing rats were used and the results of the two studies are therefore not comparable. Thus combined adrenalectomy, orchidectomy and cortisone treatment caused a pronounced interference with the normal skeletal growth and development. Also in other experimental studies where young animals have been used the reported osteoporotic bone lesions induced by excess corticosteroids seem to have been mainly the result of interference with normal skeletal development. In the present investigation on fully grown animals the hormonal disturbance exerted its effect on the maintenance of the mature skeletal tissue which is the essential problem in connection with the development of osteoporosis in humans.

It has been proposed that senile osteoporosis develops as a result of inhibited protein synthesis of the bone matrix (*Reifenstein* 1957). There is experimental evidence that cortisone primarily reduces the synthesis of bone collagen and does not increase its degradation in the rat (*Smith and Allison* 1965). Results

Histological examination of decalcified vertebral cross sections showed a regular frequency of distinct areas giving evident metachromasia with toluidine blue at pH 4.4 and located in spaces intervening between parallel fibered bone in the metaphyseal bone trabeculae and metaphyseal cortex. These metachromatic areas contained only a small amount of collagen stainable with azocarmine G. These areas seem to consist of intercellular acid mucopolysaccharides extending from the epiphyseal region inwards to the metaphysis and no such areas were observed in the diaphyseal cortex. In the experimental animals no change in staining properties of these areas was found. It is well known that excess of corticosteroids decreases the synthesis of acid mucopolysaccharides in connective tissues and that the incorporation of S^{35} sulphate into chondroitin sulphate of costal cartilage in rabbits is diminished after corticosteroid treatment (Bostrom and Odeblad 1954; Whitehouse and Bostrom 1961). In one year old rats treated with cortisone acetate in doses of 15 to 18 mg/kg for up to 8 weeks a decrease in the hexosamine contents of the whole femur was found in contrast to unchanged collagen contents and it was suggested that a decrease of mucopolysaccharides precedes the events which lead to the development of osteoporosis in Cushing's disease (Sobel and Marmorston 1954). The changes observed may be unspecific with regard to the mucopolysaccharides of the bone tissue itself and no support for this theory can be obtained from the observations made in the present study. This point is discussed further in a biochemical investigation (Larsson and Vejlsø 1969).

The results of the present study show that the skeletal tissue of one year old rats is relatively stable to the action of combined oophorectomy and prednisolone administered for up to 16 weeks. Despite a pronounced decrease in body weight there was only a slight but significant decrease of the bone tissue in animals treated for 14 and 16 weeks. This may however correspond to a considerable calcium loss in view of the effect of corticosteroids on calcium metabolism and calcium homeostasis. This is discussed further in a following study (Larsson 1969 b).

SUMMARY

In one year old rats the effect on the skeletal tissue of combined oophorectomy and prednisolone administration (15 mg/animal/day *Precortalon aq.*) for 1 to 16 weeks was studied. This treatment caused considerable depletion of adipose and muscle tissues: a total decrease in the body weight by 30 per cent and

investigation the experimental animals treated with prednisolone for 2 weeks and more showed no apparent difference in food consumption in relation to body weight compared with that of the normal controls. It is therefore hardly likely that a reduced calcium intake would be responsible for the bone reduction observed after 14 and 16 weeks of treatment.

Microscopic examination of decalcified sections of the vertebral bone from the normal adult female rats showed a high frequency of retracting osteocytes. Enlarged spherical lacunae, entirely empty or containing a pyknotic nucleus were regularly found especially in the cortical bone. These changes were unspecific and were found to the same extent in normal as in prednisolone treated oophorectomized animals. Similar morphological changes have also been observed in aged humans and have been ascribed to physiologic aging of bone (Sherman and Salkowitch 1957). In patients with severe osteoporosis these changes are more pronounced (Urist *et al* 1963). The morphologic appearance of the bone observed in the present study did not seem to be related to the reaction of the bone tissue to the treatment given.

In histological sections of vertebral bone tissue no osteoblasts or osteoclasts were found either in the normal or in the experimental rats. A small amount of bone surface showing tetracycline labelling was the only sign of low osteoblastic activity. No change was observed in the corticosteroid treated oophorectomized animals, in contrast to observations on growing animals in which excess corticosteroids regularly suppress osteoblast formation (Stanisla *et al* 1962, Hulth and Olerud 1963). In addition on administration of high doses of cortisone acetate highly increased osteoclast formation has been observed in young rabbits (deValderrama and Munuera 1965). In humans with hypercorticism the reported bone changes are not quite conclusive. Thus rarefaction of vertebral bone trabeculae with seemingly adequate numbers of osteoblasts and no evidence of osteoclastic resorption was reported by Follis (1951). Decreased formation and resorption of bone was reported by Storey (1963). Other investigators have deduced from histological (Sissons 1956) and micro radiographic (Jowsey *et al* 1965) studies that osteoporosis in human hypercorticism results from impaired new bone formation in the presence of normal or increased bone resorption. Recently an elevated number of active osteoblasts and a high uptake of tetracycline have been observed in human hypercorticism and in severe cases high osteoclastic activity (Birkenhager *et al* 1967). While in young rats excess cortisone exerts a pronounced effect on the kinetics of the bone cell populations (Simmons and Kunin 1967) there was no such effect in the old rats used in the present study.

Studies on the Development of Experimental Osteoporosis

IV The Effect of Combined Oophorectomy and Prolonged
Prednisolone Administration on the Blood Calcium Level and
the Distribution of Ca^{45} between Blood and Bone in Adult Rats

by

Sven Erik Larsson

In young rats cortisone osteoporosis similar to that in rabbits has been reported by Storey (1960). It was shown that bone rarefaction occurred only when the rats were fed a diet in which the calcium and phosphorus contents were normal i.e. 1.0 and 0.6 per cent respectively or lowered on a high calcium phosphorus intake there was an increase in the density of the metaphyseal bone. This difference in the reaction of the bone to cortisone was believed to be associated with the well developed adaptive calcium metabolism of the rat. It has been known for many years that corticoids exert considerable influence on the calcium metabolism. The skeletal retention of bone seeking isotopes has been claimed to be inhibited by the administration of corticoids to rats (Clare et al 1959, Milbrand et al 1960, Bohr and Dawids 1964). Calcium excretion has been found consistently to be increased but there is disagreement concerning the effect on intestinal calcium absorption. Young male rats subjected to bilateral adrenalectomy and orchidectomy are more sensitive to cortisone and develop osteoporosis despite a high calcium intake (Caldwell 1962). Oestradiol cured the osteoporosis in these animals despite continuous cortisone administration whereas only very slight improvement was noted in animals given testosterone.

The present study is a continuance of a previous investigation (Larsson 1969 a) and was undertaken in order to obtain some information regarding the pathomechanism underlying the observed significant reduction of bone mineral caused by the hormonal imbalance induced in adult rats by oophorectomy combined with prolonged prednisolone administration. The data to be reported here concern the effect on the blood calcium level, the distribution of Ca^{45} between blood and bone and the calcium accretion rate of the bone in the same material of oophorectomized rats kept on prednisolone treatment for different periods from 1 up to 16 weeks.

MATERIAL AND METHODS

MATERIAL

Fifty five adult female rats of the Sprague Dawley strain¹ were used. All animals were stated to be 11½ to 12 months old at the start of the experiment and had a mean initial body weight of 349.5 ± 2.7 grams. The animals were divided at random into ten experimental groups and one control group of 5 rats each. The experimental animals were oophorectomized via a midline

INTRODUCTION

Treatment with glucocorticoids causes both a negative calcium balance and loss of bone in adult humans (*Albright and Reifenstein 1948*) The pathomechanisms involved during the development of the corticosteroid induced osteoporosis are still poorly understood however The antianabolic effect of glucocorticoids on connective tissues is well known and it has been proposed from histological observations that the decrease in the amount of bone tissue in humans with Cushing's syndrome is the result of inhibited new bone formation (*Sissons 1956*) It has also been pointed out from quantitative histological studies of rib sections that bone formation is profoundly depressed in corticoid treated patients and that bone resorption also appears to be depressed but to a lesser degree than the formation (*Villanueva et al 1966*) With the aid of quantitative microradiography of sections from the iliac crest decreased bone formation and increased resorption have been demonstrated both in Cushing's syndrome and after corticosteroid therapy (*Jousey et al 1965*) The results obtained with the aid of bone seeking isotopes or stable strontium are not quite conclusive with regard to the effect of corticosteroids on the skeletal tissue Measurements of the bone mineralization rate by a variety of techniques have failed to find any consistent difference in this respect between normal and steroid treated individuals (*Nordin et al 1963 Nordin et al 1964*) Studies by means of stable strontium of a large number of patients taking synthetic steroids have revealed an increase in urinary excretion and bone accretion rate however in three cases of Cushing's syndrome small pool sizes and low turnover rates were found (*Gordan and Eisenberg 1963*) From strontium kinetic studies on corticoid treated osteoporotic patients it has been concluded that the bone accretion is normal or even increased and that the eventual decrease in bone mass is caused by accelerated bone resorption (*Eisenberg 1966*)

Osteoporosis similar to that in humans has been induced experimentally in young rabbits by excess cortisone (*Sissons and Hadfield 1955 Storey 1957*) The conclusion was drawn from histological studies that the bone rarefaction is the result of inhibited bone formation with an unopposed continuance of bone resorption (*Sissons and Hadfield 1955 Sissons 1956*) It has also been deduced from observations based on histological studies in young rabbits that cortisone osteoporosis results not only from a cessation of bone formation but primarily from a direct degrading effect which causes a massive resorption of bone (*deValderrama and Munuera 1966*)

Determination of the Ca^{45} activity of the bone

The whole right tibia including the bone marrow and the articular cartilages was carefully freed of surrounding soft tissues and periosteum. All bones were ashed simultaneously in a muffle furnace at 700°C for 16 hours, after which the ash weight was recorded with the aid of a Mettler balance and with an accuracy of 0.05 mg. All ashed bones were then dissolved in 5.0 ml of 1.2 N HCl in 100 ml volumetric flasks. When the ash was completely dissolved the flasks were filled to the mark with deionized water. An aliquot of 2.0 ml from the final solution was transferred into a 25 ml polyethylene counting vial which was filled with a gel scintillator composed of 2.5 g Diphenyloxazole (PPO), 1.0 g 1,4-bis(2,4-Methyl-5-Phenyloxazolyl) Benzene (POPOP), 0.3 g Naphthalene, 100.0 g Diuron/litre and thioxotrophic gel powder (CAB O-SIL) to saturation.

Determination of the Ca^{45} uptake of pure compact bone tissue

Acetone dried bone powder was prepared from the tubular bones as described elsewhere (Larsson 1969 b). Approximately 100 mgs of bone powder were ashed at 700°C in a muffle furnace for 16 hours. The exact ash weight was then recorded after which the ash was dissolved in 2.0 ml of 1.2 N HCl directly in the counting vials. After addition of the scintillator counting was performed.

Ca^{45} activity of plasma

This was determined directly using 1.0 ml of plasma collected at sacrifice and about 0.2 ml of plasma obtained from the tail blood collected at different intervals after the administration of the isotope. This procedure was considered suitable for the purpose of the present study (see Budy 1963) and has been recommended by Kumar (1966). The same scintillator was used as for the bone ash solutions.

Calcium determination of the plasma

This was performed by flame photometry using an Eppendorf photometer on plasma collected at sacrifice. Duplicate determinations were always performed. The error of the method was found to be less than 1 per cent.

Calcium content of the cortical bone powder

This was determined by atomic absorption spectrophotometry using an automated Perkin Elmer Model 303 Instrument as described elsewhere (Larsson 1969 b).

abdominal incision under ether anaesthesia. All the animals recovered very quickly after the operation. From the third day after oophorectomy each animal received 2.5 mg prednisolone¹ daily, dissolved in their drinking water. This was supplied intermittently in such a way that the prednisolone was consumed during the following 1–2 hours. The periods of prednisolone treatment varied from 1 up to 16 weeks. The control group consisted of normal rats and was observed for 16 weeks. The experimental and the control animals received the same ordinary laboratory food ration² and tap water *ad libitum* although, as mentioned above, the experimental animals were given their drinking water more intermittently. Chemical analyses showed that the total calcium and phosphorus in this diet amount to 1.0 and 0.55 per cent respectively. All animals were housed in individual cages in a separate room and were not exposed to sunlight. The animals could move around freely in their cages.

INVESTIGATIONAL PROCEDURES

A detailed description of the procedures used has been given in a previous paper (Larsson 1969 b). The body weight of each animal was recorded weekly. The series was planned so that all the animals were sacrificed at the same time. Seventy-two hours before sacrifice 20 microcuries of Ca^{45} in 1.0 ml physiological saline solution were injected intraperitoneally in each animal. All administered solutions were prepared from a single batch of Ca^{45}Cl . At intervals of 6, 24 and 48 hours after the isotope injection 0.4 to 0.5 ml tail blood was collected and after 72 hours the animals were sacrificed by bleeding to death from the femoral artery under ether anaesthesia. The blood samples obtained at 6 and 48 hours after the Ca^{45} injection were taken from three animals of each group and at 24 hours from the remaining two. The collected blood was centrifuged immediately at 3000 r.p.m. for 15 minutes and the plasma transferred into acid washed test tubes and kept at -20°C for later determinations of Ca^{45} activity. The whole animal bodies were kept at -20°C pending the subsequent bone preparations.

significance level When a significant result was obtained data of one or more groups were combined in order to find significant contrasts These were tested according to Sicheffe (1961) In the following the term significant will stand for statistically significant as found with the tests described above

RESULTS

All animals survived except one which was excluded The normal control rats showed a slight initial increase in body weight but after 6 weeks the body weight remained at a constant level of 5 to 7 per cent above the initial value The group of oophorectomized animals maintained on prednisolone treatment for 16 weeks showed a total loss of body weight by approximately 30 per cent of the initial value A considerable depletion of the adipose and muscle tissues was observed in all experimental animals but otherwise the animals were in good condition No infections or any other intercurrent diseases were observed

Fig 1 Plasma calcium in normal control rats and oophorectomized rats treated with prednisolone for different periods of time

For suppression of the interference by phosphorus lanthanum chloride was added to the solutions as recommended by Willis (1961). The added calcium recovery in these bone ash solutions was found to be 98 per cent. Duplicate determinations were performed throughout. The coefficient of variation for these analyses was less than 1 per cent.

Ca⁴⁵ activity determination

These were performed with the aid of a Packard Tri Carb Liquid Scintillation Spectrometer¹. Corrections were made for background and decay. It was not considered necessary to introduce any corrections for self absorption because of the constancy of counting efficiency.

Treatment of isotope data

The Ca⁴⁵ activity of bone was expressed as counts per minute per milligram of ash. No significant difference was found in the calcium content of ash obtained from pure cortical bone tissue of the normal and the treated animals; the mean calcium content was 38.09 ± 0.20 per cent. Therefore the expression c.p.m. per milligram of ash is equivalent to the specific activity and the factor 0.3809 was used when the bone accretion rates were calculated (see below). The Ca⁴⁵ activity of plasma at 72 hours after the isotope injection was expressed as c.p.m. per milligram of calcium. The plasma Ca⁴⁵ activity curves (Fig. 2) were also based upon values expressed as c.p.m. per milligram of calcium. Because of the necessity for collecting as little blood as possible at the different periods after the administration of Ca⁴⁵, calcium determinations were only performed on blood samples obtained at sacrifice.

The accretion rates for the whole tibia expressed as mg calcium/hour/mg calcium of the tibia were calculated according to Bauer *et al.* (1955). The mean values within each group were used throughout.

Statistical treatment of data

The analytical data obtained from the rats in each group were subjected to analysis of variance with one way lay-out according to Scheffe (1961). The hypothesis of no difference between groups was tested at the 5 per cent

Fig 2 Plasma Ca^{45} specific activity corrected for body weight at 6 24 48 and 72 hours after the isotope injection in normal control rats (broken line) and in oophorectomized rats treated with prednisolone for different periods of time (whole line) Each dot represent the mean value for the control group

the normal control group. At 24 48 and 72 hours after the administration of the isotope the plasma Ca^{45} activity showed consistently lower values in the experimental animals than in the normal controls.

Plasma Ca^{45} specific activity at 72 hours after the Ca^{45} injection (Fig 3 Table 2)

In comparison with the normal control group lower values were obtained in the group of oophorectomized rats treated with prednisolone for 1 week. This difference was not significant however. The two groups of animals treated for 2 and 3 weeks showed approximately the same values as the controls. In all the seven groups of oophorectomized rats kept on prednisolone treatment for 4 to 16 weeks consistently decreased values were noted. In these groups the plasma Ca^{45} activity was approximately 40 per cent lower than in the normal control group. When the combined values for these groups were tested against those of the normal control group the difference was found to be significant.

Plasma calcium (Fig 1, Table 1)

The values of the oophorectomized rats treated with prednisolone for 1, 2, 3 and 4 weeks were consistently lower than those of the control animals. In the groups of rats treated for 2 and 3 weeks the fall in plasma calcium was significant and amounted to approximately 12 per cent. The group of animals treated for 5 weeks showed normal values but, again, subnormal values were recorded in the four groups of oophorectomized rats maintained on prednisolone treatment for 8, 10, 12 and 14 weeks. This decrease was not significant, however. Finally normal plasma calcium values were found in the group of animals treated for 16 weeks.

Table 1 Plasma calcium in normal rats and oophorectomized rats treated with prednisolone for different periods of time (S.E.M. = standard error of the mean)

Plasma Ca^{45} activity at different periods after the Ca^{45} injection (Fig 2)

In all groups of oophorectomized rats treated with prednisolone for different periods of time there was a more rapid fall in plasma Ca^{45} activity than in

Ca^{45} activity of the tibia 72 hours after the Ca^{45} injection (Fig 4 Table 3)

Slightly higher values were obtained in the groups of oophorectomized rats treated with prednisolone for 1 and 2 weeks compared with those of the normal controls. This difference was not significant, however. In the group of oophorectomized rats treated for 3 weeks the values obtained showed no difference from those of the normal controls. In the groups of oophorectomized rats treated for 4 to 16 weeks successively lower bone Ca^{45} activity values were noted, decreasing with the duration of prednisolone treatment. When the combined values of the five groups of rats treated for 8 to 16 weeks were tested against those of the normal controls and the four groups of rats treated for 1 to 4 weeks the difference was found to be significant. In the groups of rats treated for 14 to 16 weeks the values were approximately 30 per cent lower than those of the normal controls.

there is a tendency towards hypercalcemia (Walser *et al* 1963) and that cortisone tends to reverse the hypercalcemia accompanying different diseases such as sarcoidosis and hypervitaminosis D (Dent 1956 Connor *et al* 1956). Adrenalectomy further gives rise to increased concentrations of blood calcium in dogs (Rogoff and Stewart 1928) rabbits (Kisch 1924) and rats (Robdenburg and Krebbiel 1925). It has been stated that hydrocortisone has no effect on the blood calcium of patients or animals with functioning parathyroids (Stoerk *et al* 1963) but lowers the blood calcium level in hypoparathyroid patients (Leifer and Hollander 1953) and in parathyroidectomized animals of several species (Mitrush and Bosman 1929 Stoerk and Arison 1961). It has also been shown that 3.5 times more parathyroid extract is needed to maintain normal blood calcium concentrations in hydrocortisone injected parathyroidectomized rats than in controls subjected to parathyroidectomy alone. The steroid had no effect on the blood calcium of normal animals (Stoerk *et al* 1963). In contrast, it has been reported that an excess of cortisone reduces the normal blood calcium level in young rats (Laron *et al* 1958 Simmons and Kunin 1967). This has also been observed in rabbits (Pincus *et al* 1951). The fall in the blood calcium level observed in the present study indicates that considerable changes in the calcium metabolism are induced in the adult rat by combined oophorectomy and prednisolone administration. After normalization following the significant decrease during the initial 2 and 3 weeks slightly subnormal values were again noted between the 8th and the 14th week of treatment, followed by further normalization.

In maintaining the blood calcium at a normal level the bone tissue has an important function as a mineral reservoir (Copp and Shim 1963). The results reported by Stoerk *et al* (1963) suggest that stimulated parathyroid function must be involved in the maintenance of the blood calcium level during cortisone administration. This would give rise to increased mobilization of skeletal calcium to the blood and these investigators suggest that this mechanism might be responsible for the cortisone induced osteoporosis. However in a study of cortisone treated still growing male rats no signs of increased parathyroid activity were observed (Hansson 1967). The initial decrease in blood calcium observed in the present study was of such an order of size that stimulated parathyroid function might well have been involved. The calcium wasting effect of corticoids is well known (Gordan *et al* 1967). The calcium retaining effect of oestradiol has been demonstrated by Caldwell (1962) in growing male rats rendered osteoporotic by combined bilateral adrenalectomy, orchidectomy and cortisone treatment. Despite continuous cortisone administration oestradiol

DISCUSSION

Corticosteroid administration to young animals always interferes with the normal bone growth (Follis 1951, Sissons and Hadfield 1955, Laron *et al* 1958, Kowalewski 1962, Stanisavljevic *et al* 1962, Hulth and Olerud 1963, Tapp 1966, Simmons and Kunin 1967). When young, still growing animals are used in studies concerning the effects of corticosteroids on the bone mineralization rate the growth inhibitory effect of the treatment must be taken into consideration. No such interference could occur in the present study since fully grown, one year old rats were used. Only a very slight initial body weight increase occurred in the normal control rats and after 6 weeks of observation the body weight remained unchanged. It has been established earlier that in mature female rats no further skeletal growth occurs after a constant body weight has been attained (Singer *et al* 1952). The pronounced decrease in body weight recorded in the experimental animals was caused by depletion of the adipose and muscle tissues due to the treatment. In a previous study (Larsson 1969 a) the effect on the skeletal tissue was examined in the material used in the present investigation. Measurements of the femur length showed no significant differences between normal and corticosteroid treated animals and the epiphyseal zones were closed. After the combined treatment with oophorectomy and maintained prednisolone administration for 14 and 16 weeks there was a significant decrease in the ash content of the whole tibia by 6 to 7 per cent which represents a considerable loss of calcium. Microradiographs of undecalcified vertebral sections showed that the bone tissue was well mineralized and there was no difference in the degree of mineralization observed on microradiographs from normal and experimental animals. It was of interest therefore, to examine the changes in calcium metabolism occurring during the process of bone reduction in these adult rats, especially since earlier work has been confined almost exclusively to the effect of corticosteroids on young growing animals where interference with skeletal growth has to be considered.

The significant fall in blood calcium observed in the groups of oophorectomized rats treated with prednisolone for 2 and 3 weeks is of especial interest. It has been reported earlier that cortisone administration does not reduce the blood calcium level or affect hypercalcemia induced by vitamin D in young rats (Williams *et al* 1962). In dogs prednisolone treatment results in a significant increase in the blood calcium by 7 per cent (Garrett *et al* 1964). This is in disagreement with observations in humans that in cases of adrenal insufficiency

there is a tendency towards hypercalcaemia (Walser et al 1963) and that cortisone tends to reverse the hypercalcaemia accompanying different diseases such as sarcoidosis and hypervitaminosis D (Dent 1956 Connor et al 1956) Adrenalectomy further gives rise to increased concentrations of blood calcium in dogs (Rogoff and Stewart 1928) rabbits (Kisch 1924) and rats (Rohdenburg and Krehbiel 1925) It has been stated that hydrocortisone has no effect on the blood calcium of patients or animals with functioning parathyroids (Stoerk et al 1963) but lowers the blood calcium level in hypoparathyroid patients (Leifer and Hollander 1953) and in parathyroidectomized animals of several species (Murlish and Bojman 1929 Stoerk and Arison 1961) It has also been shown that 35 times more parathyroid extract is needed to maintain normal blood calcium concentrations in hydrocortisone injected parathyroidectomized rats than in controls subjected to parathyroidectomy alone The steroid had no effect on the blood calcium of normal animals (Stoerk et al 1963) In contrast it has been reported that an excess of cortisone reduces the normal blood calcium level in young rats (Laron et al 1958 Simmons and Kunin 1967) This has also been observed in rabbits (Pincus et al 1951) The fall in the blood calcium level observed in the present study indicates that considerable changes in the calcium metabolism are induced in the adult rat by combined oophorectomy and prednisolone administration After normalization following the significant decrease during the initial 2 and 3 weeks slightly subnormal values were again noted between the 8th and the 14th week of treatment, followed by further normalization

In maintaining the blood calcium at a normal level the bone tissue has an important function as a mineral reservoir (Copp and Shim 1963) The results reported by Stoerk et al (1963) suggest that stimulated parathyroid function might be involved in the maintenance of the blood calcium level during cortisone administration This would give rise to increased mobilization of skeletal calcium to the blood and these investigators suggest that this mechanism might be responsible for the cortisone induced osteoporosis However in a study of cortisone treated still growing male rats no signs of increased parathyroid activity were observed (Hansson 1967) The initial decrease in blood calcium observed in the present study was of such an order of size that stimulated parathyroid function might well have been involved The calcium wasting effect of corticoids is well known (Gordan et al 1967) The calcium retaining effect of oestradiol has been demonstrated by Caldwell (1962) in growing male rats rendered osteoporotic by combined bilateral adrenalectomy orchidectomy and cortisone treatment Despite continuous cortisone administration oestradiol

DISCUSSION

Corticosteroid administration to young animals always interferes with the normal bone growth (Follis 1951, Sissons and Hadfield 1955, Laron *et al* 1958 Kowalewski 1962, Stanisavljevic *et al* 1962, Hulth and Olerud 1963, Tapp 1966 Simmons and Kunin 1967) When young still growing animals are used in studies concerning the effects of corticosteroids on the bone mineralization rate the growth inhibitory effect of the treatment must be taken into consideration. No such interference could occur in the present study since fully grown one year old rats were used. Only a very slight initial body weight increase occurred in the normal control rats and after 6 weeks of observation the body weight remained unchanged. It has been established earlier that in mature female rats no further skeletal growth occurs after a constant body weight has been attained (Singer *et al* 1952). The pronounced decrease in body weight recorded in the experimental animals was caused by depletion of the adipose and muscle tissues due to the treatment. In a previous study (Larsson 1969 a) the effect on the skeletal tissue was examined in the material used in the present investigation. Measurements of the femur length showed no significant differences between normal and corticosteroid treated animals and the epiphyseal zones were closed. After the combined treatment with oophorectomy and maintained prednisolone administration for 14 and 16 weeks there was a significant decrease in the ash content of the whole tibia by 6 to 7 per cent, which represents a considerable loss of calcium. Microradiographs of undecalcified vertebral sections showed that the bone tissue was well mineralized, and there was no difference in the degree of mineralization observed on microradiographs from normal and experimental animals. It was of interest, therefore, to examine the changes in calcium metabolism occurring during the process of bone reduction in these adult rats especially since earlier work has been confined almost exclusively to the effect of corticosteroids on young growing animals where interference with skeletal growth has to be considered.

The significant fall in blood calcium observed in the groups of oophorectomized rats treated with prednisolone for 2 and 3 weeks is of especial interest. It has been reported earlier that cortisone administration does not reduce the blood calcium level or affect hypercalcemia induced by vitamin D in young rats (Williams *et al* 1962). In dogs prednisolone treatment results in a significant increase in the blood calcium by 7 per cent (Garrett *et al* 1964). This is in disagreement with observations in humans that in cases of adrenal insufficiency

There is a tendency towards hypercalcemia (Walser *et al* 1963) and that cortisone tends to reverse the hypercalcemia accompanying different diseases such as sarcoidosis and hypervitaminosis D (Dent 1956 Connor *et al* 1956). Adrenalectomy further gives rise to increased concentrations of blood calcium in dogs (Rogoff and Stewart 1928) rabbits (Kisch 1924) and rats (Robdenburg and Krehbiel 1925). It has been stated that hydrocortisone has no effect on the blood calcium of patients or animals with functioning parathyroids (Stoerk *et al* 1963) but lowers the blood calcium level in hypoparathyroid patients (Leifer and Hollander 1953) and in parathyroidectomized animals of several species (Mirush and Bosman 1929 Stoerk and Arison 1961). It has also been shown that 35 times more parathyroid extract is needed to maintain normal blood calcium concentrations in hydrocortisone injected parathyroidectomized rats than in controls subjected to parathyroidectomy alone. The steroid had no effect on the blood calcium of normal animals (Stoerk *et al* 1963). In contrast it has been reported that an excess of cortisone reduces the normal blood calcium level in young rats (Laron *et al* 1958 Simmons and Kunin 1967). This has also been observed in rabbits (Pincus *et al* 1951). The fall in the blood calcium level observed in the present study indicates that considerable changes in the calcium metabolism are induced in the adult rat by combined oophorectomy and prednisolone administration. After normalization following the significant decrease during the initial 2 and 3 weeks slightly subnormal values were again noted between the 8th and the 14th week of treatment followed by further normalization.

In maintaining the blood calcium at a normal level the bone tissue has an important function as a mineral reservoir (Copp and Shinn 1963). The results reported by Stoerk *et al* (1963) suggest that stimulated parathyroid function might be involved in the maintenance of the blood calcium level during cortisone administration. This would give rise to increased mobilization of skeletal calcium to the blood and these investigators suggest that this mechanism might be responsible for the cortisone induced osteoporosis. However in a study of cortisone treated still growing male rats no signs of increased parathyroid activity were observed (Hansson 1967). The initial decrease in blood calcium observed in the present study was of such an order of size that stimulated parathyroid function might well have been involved. The calcium wasting effect of corticoids is well known (Gordan *et al* 1967). The calcium retaining effect of oestradiol has been demonstrated by Caldwell (1962) in growing male rats rendered osteoporotic by combined bilateral adrenalectomy orchidectomy and cortisone treatment. Despite continuous cortisone administration oestradiol

DISCUSSION

Corticosteroid administration to young animals always interferes with the normal bone growth (*Follis 1951, Sissons and Hadfield 1955, Laron et al 1958, Kowalewski 1962, Stanisavljevic et al 1962, Hulth and Olerud 1963, Tapp 1966, Simmons and Kunin 1967*). When young, still growing animals are used in studies concerning the effects of corticosteroids on the bone mineralization rate the growth inhibitory effect of the treatment must be taken into consideration. No such interference could occur in the present study since fully grown one year old rats were used. Only a very slight initial body weight increase occurred in the normal control rats and after 6 weeks of observation the body weight remained unchanged. It has been established earlier that in mature female rats no further skeletal growth occurs after a constant body weight has been attained (*Singer et al 1952*). The pronounced decrease in body weight recorded in the experimental animals was caused by depletion of the adipose and muscle tissues due to the treatment. In a previous study (*Larsson 1969 a*) the effect on the skeletal tissue was examined in the material used in the present investigation. Measurements of the femur length showed no significant differences between normal and corticosteroid treated animals and the epiphyseal zones were closed. After the combined treatment with oophorectomy and maintained prednisolone administration for 14 and 16 weeks there was a significant decrease in the ash content of the whole tibia by 6 to 7 per cent which represents a considerable loss of calcium. Microradiographs of undecalcified vertebral sections showed that the bone tissue was well mineralized, and there was no difference in the degree of mineralization observed on microradiographs from normal and experimental animals. It was of interest therefore to examine the changes in calcium metabolism occurring during the process of bone reduction in these adult rats, especially since earlier work has been confined almost exclusively to the effect of corticosteroids on young growing animals where interference with skeletal growth has to be considered.

The significant fall in blood calcium observed in the groups of oophorectomized rats treated with prednisolone for 2 and 3 weeks is of especial interest. It has been reported earlier that cortisone administration does not reduce the blood calcium level or affect hypercalcemia induced by vitamin D in young rats (*Williams et al 1962*). In dogs prednisolone treatment results in a significant increase in the blood calcium by 7 per cent (*Garrett et al 1964*). This is in disagreement with observations in humans that in cases of adrenal insufficiency

reported by *Clark and Roth* (1961) and to an inhibitory effect of the corticosteroids on normal bone growth resulting in decreased bone mineralization (see below) In dogs prednisolone increases the amount of intravenously administered Ca^{45} eliminated in the faeces and urine (*Collins et al* 1962) and in man cortisone and ACTH increase the calcium excretion in both the urine and faeces (*Luft and Sjogren* 1951) The tubular reabsorption of calcium is reduced in humans treated with corticosteroids possibly due to an anti anabolic effect on the cells of the tubules (*Laake* 1960) The effect of adrenal cortical steroids on intestinal calcium absorption in the rat has been a subject of disagreement According to *Milhaud et al* (1960) corticosteroids decrease calcium absorption However no effect of hydrocortisone on the overall gastrointestinal calcium absorption was found in the rat by *Clark and Smith* (1964)

Administration of hydrocortisone to rats has been reported to inhibit the uptake of Ca^{45} by bone which was also found to be decreased in nephrectomized rats and it was suggested that the limiting factor may lie in the synthesis of chondroitin sulphate (*Clark et al* 1959) Similar conclusions were drawn from the observation that the retention by the rat of injected radioactive strontium and calcium measured over the total body and over the tail was decreased after the administration of dexamethasone (*Bohr and Dawids* 1964) The specific activity of the blood was not determined but because the specific activity of the urine was increased while the urinary output of calcium was normal it was suggested that the decreased retention was due to a reduction in the amount of bone available for mineralization In both these studies interference by the corticosteroids with normal growth might well explain the results obtained especially in the experiment of *Clark et al* (1959) where male rats weighing between 160 and 250 gms were used *Bohr and Dawids* (1964) used female rats weighing about 200 gms and in these animals cortisone administration caused a relatively small though definite decrease in the retention of bone seeking isotopes

In the present study the calculated mean accretion rate for the tibia was found to be increased in the groups of oophorectomized animals treated with prednisolone for 1 and 2 weeks while in the groups of rats treated for 3 to 12 weeks approximately normal values were found The groups treated for 14 and 16 weeks showed fluctuating values The experimental results are in agreement with those obtained after administration of various corticoids to normal human volunteers in whom the bone accretion rate did not fall but remained normal or even increased slightly (*Gordan and Eisenberg* 1963) The proposals made by *Clark et al* (1959) and by *Bohr and Dawids* (1964) may be

cured the osteoporotic bone changes in these animals. In the rat but not in other species, oestrogens have been reported to inhibit bone resorption (Budy *et al* 1952, Lindquist *et al* 1960). In the present study the significant fall in the blood calcium level was induced by the combination of oophorectomy which resulted in a reduced production of endogenous oestrogens, and daily administration of prednisolone. This caused a significant decrease in the mineral content of the whole tibia after treatment for 14 and 16 weeks (Larsson 1969 a). The contradictory results obtained in earlier studies concerning the effect of excess corticosteroids on the blood calcium level might be explained by the present findings indicating that during the progress of the treatment periods of decreased blood calcium values are followed by periods of normal values. Furthermore the combination of oophorectomy and prednisolone treatment might have a more pronounced blood calcium lowering effect than corticosteroid treatment alone.

The plasma Ca^{45} activity curves indicate an increased elimination rate of intraperitoneally administered Ca^4 from the blood in the experimental groups in comparison with that of the normal control group. On examination of the Ca^{45} activity values of the plasma and the tibia at 72 hours after the isotope injection it is seen that the group of rats treated for 1 week showed decreased plasma Ca^4 activity and slightly increased Ca^4 activity in the bone. The rats treated for 2 weeks showed approximately normal plasma Ca^{45} activity but slightly increased bone Ca^{45} activity and the group treated for 3 weeks showed approximately the same values for both the plasma and bone Ca^{45} activity as those of the normal control group. The groups of rats treated for 4 to 16 weeks showed concomitant decreases in the plasma and bone Ca^{45} activity values in spite of the fact that with consideration of their body weights these animals were injected with a higher dose of Ca^{45} than the normal controls. The Ca^{45} activity of compact bone tissue showed the same decrease as that of the whole tibia although the uptake of Ca^4 by the compact bone only amounted to less than one fifth of that of the whole tibia. These data indicate that prednisolone administration to oophorectomized mature rats results in increased calcium excretion and decreased calcium retention progressing with the duration of prednisolone treatment. The decrease observed in the blood calcium level seems to be secondary to poor or retarded adaptation to the increased calcium excretion.

It has been reported that corticosteroids increase the excretion of administered bone seeking isotopes in young rats (Clark *et al* 1959, Milbrand *et al* 1960, Bohr and Dawids 1964, Clark and Smith 1964). In young growing animals this might be due to decreased reabsorption of calcium by the renal tubules as

All the seven groups of rats treated for 4 to 16 weeks showed consistently decreased values for both the plasma and bone Ca^{45} activity

The Ca^{45} activity of compact bone powder was appreciably lower than that of the whole tibia. In the three groups of rats treated for 1, 2 and 3 weeks the former activity showed approximately the same values as those of the normal control group. In the seven groups of rats treated for 4 to 16 weeks consistently decreased values were obtained with a maximum reduction in the groups of animals treated for 12, 14 and 16 weeks.

The calculated calcium accretion rate for the tibia expressed as mg calcium/hour/mg calcium of the tibia showed increased mean values in the groups of rats treated for 1 and 2 weeks compared with that of the normal control group. The six groups of oophorectomized rats treated with prednisolone for 3 to 12 weeks showed approximately the same mean values as that of the normal control group. In the group treated for 14 weeks a lower mean accretion rate was found while it was higher in the group of animals treated for 16 weeks compared to that of the control group.

The presented data show that the hormonal imbalance induced in adult rats by combined treatment with oophorectomy and prolonged prednisolone administration evidently results in increased calcium deprivation because of increased excretion progressing with the duration of prednisolone treatment. There was an increased elimination from the blood of intraperitoneally administered Ca^{45} and a corresponding decrease in the uptake of Ca^{45} by bone. Except for an initial increase the calcium accretion rate by bone was approximately the same in the experimental and control rats. These data indicate indirectly that the significant reduction of bone tissue observed in the same material and reported elsewhere was caused by increased bone resorption which would mobilize skeletal calcium to the blood to normalize the observed significant fall in the blood calcium level.

valid with regard to young still growing animals. However, in the skeleton of the adult rat in which calcification and growth are completed, the accretion rate was normal or even increased after combined oophorectomy and corticosteroid administration. This implies that the induced hormonal imbalance did not exert any appreciable inhibitory effect on the bone mineralization rate. Evidence was obtained in this investigation to indicate that the decreased skeletal uptake of intraperitoneally administered Ca^{45} is the result of increased elimination of Ca^{45} from the blood due to increased excretion brought about by the treatment. The data presented here strongly suggest that the slight reduction of the bone tissue found in a previous study (Larsson 1969 a) was caused by increased bone resorption which would mobilize skeletal calcium for maintenance of the blood calcium level. With extension of the periods of prednisolone treatment a more pronounced osteoporosis would develop, due to the continuous calcium loss.

SUMMARY

Ten groups of 5 fully grown one year old female rats were oophorectomized and then treated with prednisolone for periods varying from 1 up to 16 weeks. One control group of 5 normal rats was kept on the same normal laboratory ration for 16 weeks. A total loss of body weight by approximately 30 per cent was observed in the group of oophorectomized rats treated with prednisolone for 16 weeks. In the normal control rats the body weight showed a slight initial increase but thereafter it remained almost constant throughout the observation period of 16 weeks.

The plasma calcium showed a significant fall in the groups of rats treated for 2 and 3 weeks. In the group treated for 5 weeks normal values were noted. In rats treated for 8 to 14 weeks subnormal plasma calcium values were observed while in the group of rats treated for 16 weeks the values were again normal.

There was a higher elimination rate of intraperitoneally administered Ca^{45} from the blood in the experimental groups in comparison with that of the control group. The Ca^{45} specific activity of plasma at 72 hours after the isotope injection was significantly decreased in the group of rats treated for 1 week while there was a concomitant tendency to an increase in the Ca^{45} activity of bone. In the group of rats treated for 3 weeks the Ca^{45} activity of both plasma and bone showed values similar to those of the normal group.

regarding the quantitative and qualitative relationships of the glycosaminoglycans in the compact bone tissue of adult rats during the development of two types of experimental osteoporosis induced by (1) oophorectomy combined with prednisolone treatment or (2) prolonged calcium restriction. The material was analysed mainly by methods based on the solubility properties of the glycosaminoglycan complexes with cetylpyridinium. By adapting the technique of Antonopoulos *et al* (1964) information was obtained on the distribution of the chondroitin sulphate with regard to molecular size. The isolated chondroitin sulphate was further characterized by physical and chemical methods. In addition the concentrations in compact bone tissue of glycosaminoglycans, hexosamines, hydroxyproline, ash and calcium were determined in normal conditions and during the development of these two different types of osteoporosis.

MATERIAL

1 Compact bone tissue of normal and prednisolone treated oophorectomized adult rats

Fifty five adult female rats of the Sprague Dawley strain¹ were used. All the animals were 11½ to 12 months old at the start of the experiment and had a mean initial body weight of 348.5 ± 27 grams. The material was divided at random into ten experimental groups and one control group with 5 rats in each. The experimental animals were first oophorectomized via a midline abdominal incision under ether anaesthesia. All these animals recovered very quickly after the operation. From the third day after the oophorectomy each animal was given 2.5 mg prednisolone² daily dissolved in their drinking water, which was supplied intermittently in such a way that the prednisolone was consumed during the following 1–2 hours. All animals were housed in individual cages. The periods of treatment varied from 1 to 16 weeks. The control group consisted of 5 normal rats and was observed for 16 weeks. The experimental and the control animals received the same ordinary laboratory food ration³ and tap water. All animals except one survived through the

INTRODUCTION

Very little is known about the function of the bone glycosaminoglycans. It has been suggested that chondroitin sulphate plays a role in the mineralization stage during bone formation (Climcher 1959, Sobel *et al* 1960) but opinions are divergent.

The formation of glycosaminoglycans of connective tissues appears to be under endocrine control (for *ret* see Brunish 1966). An inhibitory effect of corticosteroids on the synthesis of glycosaminoglycans in different connective tissues has been demonstrated both *in vitro* and *in vivo*. In view of the decrease observed in S^{35} sulphate incorporation into the chondroitin sulphate of rib cartilage (Bostrom and Odeblad 1954, Whitehouse and Bostrom 1961) some influence also on bone tissue glycosaminoglycans could be anticipated. However, the effect of excess corticosteroids on the glycosaminoglycans in adult bone tissue does not appear to have been studied. From the finding of a decrease in the ratio of total hexosamine to collagen in the whole femur of one year old rats it has been suggested that corticosteroids reduce the content of glycosaminoglycans in bone, which would precede the events leading to the development of osteoporosis (Sobel and Marmorston 1954). However these results cannot be interpreted as an effect on bone tissue glycosaminoglycans alone since the articular cartilage of the femur, with its high content of glycosaminoglycans was also included in the specimens. Furthermore the total hexosamine content does not reflect the glycosaminoglycan content alone.

In human osteoporosis, changes in bone matrix have been reported from studies with the aid of X ray diffraction and electron microscopy (Little *et al* 1962). Decreased hydroxyproline contents have been found in bone specimens from the iliac crest in osteoporotic subjects (Birkenhaefer Frenkel 1966). With biochemical methods, Casuccio *et al* (1962) noted a decrease with age in protein nitrogen and hexosamines, and changes in the glucosamine/galactosamine ratio in several fractions of vertebral bone tissue extracted according to the method of Dische *et al* (1958). The significance of these findings in relation to the osteoporotic process and to a possible role of glycosaminoglycans in this connection is far from clear.

The present investigation was undertaken in order to obtain information

METHODS

Hexosamine was determined by the Elson and Morgan reaction as described by *Antonopoulos et al* (1964) except that a 1/2 scaled down procedure was used in most cases

Aminosugar was characterized by the Dowex 50 H column chromatographic procedure of *Antonopoulos* (1966)

Uronic acid was determined by the carbazol method of *Dische* (1947)

Sulphate was determined by the benzidine method as described by *Antonopoulos* (1962)

Calcium in bone powder was determined by atomic absorption spectrophotometry using a Perkin Elmer Model 303 Instrument. About 50 mg of bone powder was ashed at 700°C in a muffle furnace for 16 hours. The ash was weighed on a Mettler balance with an accuracy of 0.05 mg and the percentage ash content calculated. The ash was then dissolved in 10 ml of 1.2 N hydrochloric acid. After dilution to the desired calcium concentration a 5% lanthanum solution in 25% (v/v) HCl was added so that the final calcium concentration was within the optimum working range of 1 to 10 ppm and with 0.5% lanthanum (see Perkin Elmer Rev. May 1966). In this way the calcium/lanthanum ratio was 1/1000 as recommended by *Willis* (1961) for depression of the phosphorus interference. The added calcium recovery in these bone ash solutions was found to be 98 per cent. Duplicate determinations were performed throughout. The coefficient of variation for these analyses was less than 1 per cent.

Hydroxyproline was determined by the method of *Neuman and Logan* (1950). The coefficient of variation for these determinations was 2 per cent.

*Susceptibility to testicular hyaluronidase*¹ was tested by the procedure described by *Solheim* (1965).

period of observation. There were no signs of infections or any other intercurrent diseases. The experimental animals lost about one third of their initial body weight. The femur length was the same as in the normal animals which confirmed that no interference with skeletal growth had occurred.

The series was planned so that all the animals were sacrificed at the same time. This was performed by bleeding them to death from the femoral artery under ether anaesthesia. Immediately after sacrifice the animals were placed in a deep freezer at -20°C pending the preparations of the long tubular bones. The bones were carefully dissected free from soft tissues and periosteum. The epiphyses including the cartilage, were removed using a bandsaw. The diaphyses were split into small bone fragments which were carefully cleaned from bone marrow with no use of solvents. The bone fragments were further defatted and dehydrated with 5 changes of acetone for 3 days. The material was finally air dried and then pulverized in an Intermediate model Wiley Laboratory Mill provided with a 60 mesh sieve. The defatted dry bone powder obtained was stored in containers with snap caps pending the subsequent analyses.

2 Compact bone tissue of normal and calcium deficient adult male rats

Forty one adult male rats of the Sprague Dawley strain¹ were used. The experimental animals were 12 to 12½ months old at the start of the treatment and were divided into seven groups. The control group consisted of five 21 month old rats. The mean initial body weight of all rats was 505.2 ± 8.2 grams. All animals had been bred on a diet with an optimal intake of calcium, phosphorus and vitamin D. The experimental animals received a calcium deficient diet² containing 0.09 per cent Ca, 0.55 per cent P and 2.0 per cent cod liver oil. The animals of the experimental groups were supplied with diet and deionized water *ad libitum* for 3 weeks and 6, 7, 8, 9, 10 and 12 months respectively. The control group received a normal laboratory ration³ containing 1.0 per cent Ca and 0.75 per cent P. All animals were kept in a sunless room. Five deaths occurred among the experimental animals, probably related to high age. Three of these animals, which were frozen immediately after death after 4–6 months on a calcium deficient diet, were included in the study, however. The bones were prepared and the bone powder was produced as described above.

*Infrared spectrophotometry*¹ was carried out using a Unicam SP 200 spectrophotometer. The KBr pellet technique was used.

Determination of total hexosamine concentration

Hexosamine determination (see above) was performed after hydrolysis of 5 mg bone powder in 1 ml of 6 N HCl for 8 hours. After evaporation of the acid, the residue was dissolved in 0.5 ml of water. The coefficient of variation was 3 per cent. (The residue sometimes contained fine black brown particles. Therefore, in some series of determinations 20 mg powder was hydrolysed instead, the residue was dissolved in 2 ml of water and after filtration through a paper² the hexosamine was determined on 0.5 ml aliquots. The values were the same as when filtration was omitted.)

For determination of hexosamine in tissues, Boas (1953) recommended an ion exchange step to eliminate non specific chromogens. In the case of bone hydrolyzed as described above, this step can be omitted as no such chromogens were found.

Determination of the concentration of CPC-precipitable glycosaminoglycans

In a 10 ml volume flask about 45 mg of bone powder was digested at 65°C in about 9 ml of a digestion mixture containing EDTA (pH adjusted to 7 with NaOH), cysteine HCl and recrystallized papain³ suspension to concentrations of 0.075 M, 0.005 M and 1–2 per cent respectively. After 3–6 hours when a clear solution was obtained the volume was brought to the mark with water and the contents thoroughly mixed. Three aliquots of 3.0 ml each were pipetted into test tubes. 4 ml of a half per cent (w/v) aqueous CPC⁴ solution was added to each and the precipitate allowed to settle over night. The precipitate was recovered by centrifugation and meticulous decanting and after hydrolysis and evaporation hexosamine determinations were made.

Determinations on aliquots from a digest of larger quantity showed a coefficient of variation of 3 per cent.

² Munktell's No. OOH S1 80 90.

³ Worthington 18.8 mg protein per ml.

⁴ CPC special grade, AB RECIP, Stockholm, Sweden.

In test experiments, when different amounts (20-50 mg) of bone powder were digested it was found that the amount of hexosamine containing material precipitated from 2 or 3 ml of digest was directly proportional to the amount of bone powder digested (Fig. 1)

Fig. 1
Amount of hexosamine (expressed as absorbance) in CPC-precipitate per ml of digest various amounts of bone powder were digested. Each point represents the mean of one 2 ml and two 3 ml aliquots from one digest (except the 45 mg digest, where the mean of one 2 ml and one 3 ml aliquot was used)

Microfractionation of glycosaminoglycans

About 75 mg of bone powder pooled from all animals within each group was digested at 65°C in 50 ml of a digestion mixture containing EDTA, cysteine HCl and papain suspension to concentrations of 0.2 M, 0.005 M and 1 protease unit respectively for 3-4 hours. After dilution with 8 volumes of water a volume of a 1 per cent aqueous solution of CPC was added and the resulting precipitate allowed to settle over night. The precipitate was collected by centrifugation in a 100 ml glass tube washed with redistilled water and dried for about half an hour in a desiccator. 400 µl of a 60 per cent (v/v) aqueous solution of n-propanol was added and the precipitate brought into solution by stirring with a glass rod. A fine-disperse residue remained undissolved and was centrifuged down. From the clear supernatant 50 µl aliquots were transferred by a constriction pipette to CPC cellulose microcolumns and were fractionated according to the method of Antonopoulos *et al.* (1964) with the following eluants: 1 per cent CPC, 0.30 M NaCl, MgCl₂ solutions with step-wise increasing concentrations from 0.30 to 0.75 M and finally 6 M HCl. The salt solutions contained 0.05 per cent CPC.

The fine disperse material, which could not be dissolved in the aqueous propanol was found in test experiments to contain only a few per cent of the whole hexosamine content of the solution. When supernatant propanol aliquots were fractionated at the same time as aliquots with undissolved matter stirred up the resulting solubility profiles did not differ noteworthy and recoveries in both cases were about 90 per cent. Centrifugation was preferred in the final procedure because of a tendency to clogging in the columns when uncentrifuged solutions were used.

Isolation and fractionation of bone glycosaminoglycans on the macroscale

The procedure used by Hjertquist and Vejlens (1968) was followed essentially. Digestion was performed as described above with 50 ml of digestion mixture per g (3—15) bone powder. Eight volumes of water and one volume of a 1 per cent CPC solution were added and after 48 hours the precipitate formed was collected on glass filter paper¹ in a Buchner funnel. It was subsequently dissolved in 65 per cent aqueous propanol (The paper was minced in the propanol solution which was then sucked out through a new glass filter until the minced paper was dry). To the clear solution 3 volumes of ethanol were added and the sodium salts of glycosaminoglycans were precipitated by adding a few ml of saturated sodium acetate aqueous solution. The precipitated material was recovered by centrifugation and dried with ethanol and ether. The powder was dissolved in water and small amounts of undissolved matter were spun down and discarded. To the supernatant (3—4 ml) as much of a 2 M NaCl solution was added so as to obtain a final concentration of 0.02 M NaCl after the addition of approximately two volumes of a 1 per cent CPC solution. On the following day the precipitated complexes were recovered by centrifugation, washed, dried for half an hour in a desiccator and dissolved in 60 per cent propanol. A small amount of substance remained undissolved. This was suspended and the solution placed on top of a CPC cellulose column, prepared according to Antonopoulos *et al* (1961). Dimensions of columns: 1 × 25 cm for 25—40 mg dried polysaccharide; 1 × 15 cm for 10 mg. Elution was performed with 1 per cent CPC, 0.3 M NaCl, 0.3 M MgCl₂ and 0.83 M MgCl₂ and finally in some cases 1.0 M MgCl₂. All salt solutions contained 0.05 per cent CPC. The collection of fractions, detection of peaks (by CP complex precipitation) and

¹ Whatman GF 81

recovery of sodium salts of the glycosaminoglycans were performed as described by Antonopoulos *et al* (1965)

Statistical methods

The analytical data obtained from the rats in each group were subjected to analysis of variance with one way lay out according to Scheffe (1961) The hypothesis of no difference between groups was tested at the 5 per cent significant level When a significant result was obtained data of one or more groups were combined in order to find significant contrasts These were tested according to Scheffe (1961)

RESULTS

Contents of ash calcium and hydroxyproline

The major components of the defatted dried bone powder i.e mineral and collagen were examined by determinations of the ash calcium and hydroxyproline contents In order to reduce the effects of small methodological variations from one occasion to another all samples at each investigation were treated at the same time whenever possible (e.g. ashing procedure weighing calcium determinations and hydrolysis) otherwise the samples were taken at random for the analyses

In the corticosteroid experiment the ash and calcium contents showed slightly lower values in the three groups of animals treated for 1 to 3 weeks than in the normal control group (Table 1) When the values for these groups combined were tested against those of the normal control group the differences were statistically significant in the case of calcium however only when the groups treated for 2 and 3 weeks were combined In the seven groups of rats treated for 4 to 16 weeks no significant changes were found however The hydroxyproline contents for treated groups showed slightly fluctuating values as compared with those of the control group but the variations were not statistically significant In the calcium deficiency experiment no significant changes were noted in the concentrations of ash calcium or hydroxyproline (Table 2)

Table 4. The concentrations of total hexosamines and C.I.C. (reduced glycosaminoglycans (as hexosamines) in compact bone powder from rats fed a normal laboratory ration and a low calcium diet for different periods of time

The sum of the $MgCl_2$ fractions (the chondroitin sulphate fraction) constituted about 94 per cent of the eluted hexosamines. The means of the values of the $MgCl_2$ fractions from the three columns were used for constructing solubility profiles. In every fractionation experiment two different groups were investigated at the same time and thus tested against each other as shown in Table 5.

Table 5 Groups tested pair wise with the microfractionation procedure

ST 10 w ST 3 w	ST 8 w ST 14 w	CaD 6 m CaD 10 m	SC ST 16 w
CaC CaD 12 m	CaD 8 m ST 2 w	CaC ST 2 w	CaC CaD 3 w

w = weeks m = months ST = steroid treatment CaD = calcium deficiency
SC = control group steroid experiment CaC = control group calcium deficiency experiment

Two of the groups (ST 2 w CaC) were tested 2 or 3 times against different groups. As the two solubility profiles emanating from microfractionations performed simultaneously were always nearly identical, it is concluded that there were no differences in the solubility properties of the CP chondroitin sulphate from the different groups. When profiles from fractionations performed on different occasions were compared, deviations were noted increasing with time and eventually becoming larger than expected on the basis of the reproducibility found previously. An increasing parallel shift to the right of the CP-chondroitin sulphate solubility curves was noted. Control fractionations showed that this phenomenon was due to a change with time of the solubility properties of the $MgCl_2$ solutions, which was not reflected in the titrated Cl^{2-} ion concentrations. This phenomenon might possibly have been caused in some way by the storage of salt solutions in small (10 ml) sealed glass bottles with rubber stoppers (the intention was to minimize evaporation) as such effects have not been seen in other studies when the salt solutions have been stored instead in larger plastic bottles with screw caps.

Total hexosamine concentration

The determinations of the total hexosamine concentration were performed on bone powder from the individual rats. About twenty 20 mg samples or fifty 5 mg samples of bone powder were weighed and analysed simultaneously. In the calcium-deficiency experiment the 5 mg sample analysis was used throughout. Duplicate analyses were performed in approximately one third of the material. In the corticosteroid experiment the two groups of rats treated for 1 and 2 weeks showed slightly increased values (Table 3). This increase was not statistically significant, however. The eight groups of animals treated with prednisolone for 3 to 16 weeks showed no consistent change which could be correlated to the duration of treatment but only a small, insignificant intergroup variation.

In the calcium deficiency experiment the values of the eight experimental groups did not differ significantly from those of the control group (Table 4).

Concentration of glycosaminoglycans

The glycosaminoglycan concentration determinations were also performed on bone powder from individual animals. Nine samples randomly selected within each of the experimental series were digested and precipitated at the same time. Hydrolysis and the remaining steps of the procedure were carried out on 9 or 18 samples simultaneously. The results are presented in Tables 3 and 4.

No statistically significant differences were found between the various groups within each experimental series. No change with the duration of treatment was noted. The hexosamines emanating from glycosaminoglycans corresponded to less than a third of the total hexosamines.

Microfractionation of bone glycosaminoglycans

In this case 750 mg of pooled bone powder consisting of equal parts from each of the rats in separate experimental and control groups were used. Three columns were run for each group. The recovery was found to be between 90 and 110 per cent.

The fractions eluted with 1 per cent CPC and 6 M HCl only occasionally contained traces of hexosamine.

The 0.3 M NaCl fraction constituted about 6 per cent of the sum of the eluted hexosamines and no differences were noted between the control and treated groups.

Isolation and characterization of chondroitin sulphate

This was performed on a pool of bone powder from each of the following groups: male control group (calcium deficiency experiment), female control group (corticosteroid experiment), calcium deficient groups (from 6 to 12 months on low calcium intake) and prednisolone treated oophorectomized groups (8 to 16 weeks of treatment). The two latter pools comprised 15 g of bone powder each while that of the control group in the calcium deficiency experiment comprised 9 g and in the corticosteroid experiment 3 g. The crude isolated glycosaminoglycans amounted to approximately 40 mg from each of the pools of the treated groups and 20 and 10 mg respectively from those of the control groups. In every column separation peaks were eluted in the following three salt solutions used: 0.3 M NaCl, 0.3 M MgCl₂ and 0.83 M MgCl₂ none in 1% CPC or 1 M MgCl₂. The fractions eluted with 0.3 M NaCl and obtained from the experimental groups in the two series were combined. The precipitated material from the corresponding fractions of the control groups was too small for analysis. The fractions eluted with 0.3 M MgCl₂ which were recovered from the control groups were combined. The amounts isolated as Na salts and the results of chemical and physical characterization of the fractions are given in Table 6. For all the fractions eluted with 0.83 M MgCl₂ the results are in accordance with chondroitin 4 sulphate with a similar degree of sulphation. The analytical results of the 0.3 M NaCl fractions and the 0.3 M MgCl₂ fractions are not wholly conclusive. It is considered however that the glycosaminoglycans in these fractions constituted a mixture of hyaluronic acid and low molecular and/or low sulphated chondroitin sulphate, the former predominating in the NaCl fractions and the latter in the 0.3 M MgCl₂ fractions. Corresponding fractions isolated from cortical bone from dogs (*Hjerquist and Vejens* 1966, 1968) have been shown to contain hyaluronic acid and a mixture of hyaluronic acid and chondroitin sulphate respectively.

DISCUSSION

Isolation of glycosaminoglycans from tissues by means of papain digestion in the presence of EDTA followed by precipitation of the liberated glycosaminoglycans with cetylpyridinium chloride is now a well established technique. As shown by *Hjerquist and Vejens* (1968) this procedure can also be used for

Table 6 Chemical and physical characteristics of the various glycosaminoglycan fractions isolated from rat corneal bone

Fraction	Amount isolated	Per cent of dry weight			Hexuronic acid ¹	Per cent of			Infrared pattern in accordance with

² Molar ratios with hexuronic acid = 1.00

be provided that the EDTA content of the digestion mixture is high enough to chelate the bone calcium. In this latter study chondroitin sulphate amounting to 0.14–0.18 per cent on the basis of total dry weight was isolated from compact dog bone. The amount of chondroitin sulphate isolated from compact rat bone in the present study was only 0.07–0.08 per cent on the same basis. These lower values can partly be explained by the higher mineral content of rat bone as compared with dog bone. Further a higher percentage loss of chondroitin sulphate during the isolation and purification procedures in the present study is likely because of the smaller amount of initial material available than was used in the investigation by Hjertquist and Vejlens (1968).

Other investigations have shown that chondroitin 4 sulphate is the predominant glycosaminoglycan of compact bone tissue from ox (Meyer *et al.* 1956) dog (Hjertquist and Vejlens 1968) rabbit and homo (Vejlens unpublished). Also in the rat bone studied in the present investigation the main glycosaminoglycan was a sulphated galactosaminoglycan with characteristics of chondroitin 4 sulphate.

The original procedure for microfractionation of CP glycosaminoglycans described by Antonopoulos *et al.* (1964) was developed on cartilage and allowed a simultaneous quantitative and qualitative analysis. Because of the low content of glycosaminoglycans and the high mineral content of the bone tissue examined in the present study quantitative analyses were performed separately from the microfractionation. The quantitative determination of the bone glycosaminoglycans as CPC precipitable components of a papain digest is a relatively simple procedure. It appears less tedious than the method described by Bollet (1958) in which no proteolysis is used, protamine is the precipitating agent and dialysis steps are included. In the present investigation the amount of bone powder used for the quantitative analyses of the glycosaminoglycans was approximately 50 mg which allowed triple hexosamine determinations from one digest. If required a single determination can be performed on only 10–12 mg of bone powder. In that case the digestion, precipitation and the Elson and Morgan reaction are carried out in the same test tube.

Only a minor proportion of the total hexosamines in compact bone tissue originates from acid glycosaminoglycans — in the rat bone analysed in the present study less than a third. The major part seems to be associated with glycoproteins (Herring 1964; Burckard *et al.* 1966).

In the present study the microfractionation procedure of Antonopoulos *et al.* (1964) was adapted to allow relatively small amounts of bone powder to be analysed for the construction of solubility profiles of CP chondroitin sulphate.

Fig. 2 Some representative solubility profiles of the CP chondroitin sulphate. Amount of hexosamine expressed as percentage of total hexosamines eluted with $MgCl_2$ solvents. Upper profiles left SC right ST 16 w. Middle profiles left SC right CaD 12 m. Lower profiles left ST 2 w right CaD 8 m. (For notation see Table 5). Note the almost identical appearance of solubility profiles on the same horizontal line which are from microfractionations performed in parallel.

In previous studies (Larsson 1969 c, d) data obtained with the aid of Ca^{45} indicated increased mobilization of skeletal calcium for maintenance of the blood calcium level both after combined oophorectomy and prednisolone administration and after prolonged calcium restriction. The results of the present investigation show that during this process of prolonged increased bone resorption the remaining compact bone tissue is quite unchanged with regard to its major components and also to the glycosaminoglycans even after combined oophorectomy and prednisolone treatment for 16 weeks or maintained calcium restriction for up to 1 year. Apart from an unchanged concentration there is no change in the molecular weight distribution of the bone chondroitin sulphate as indicated by unchanged solubility profiles at a similar grade of sulphonation.

The lack of an apparent corticosteroid effect on the glycosaminoglycans of mature bone tissue is further supported by results obtained in a short term study of almost fully mature rabbits treated for 3 weeks with other glucocorticosteroids, i.e. dexamethasone 0.5 mg/kg body weight daily or cortisone 3 mg/kg daily. The concentrations of total hexosamine, glycosaminoglycans, hydroxyproline and calcium did not differ from those of control animals and neither did the solubility profiles of the CP complexes of chondroitin sulphate (Veijens unpublished).

These findings suggest that the treatments employed did not cause any changes of the glycosaminoglycans in the bone in any case not in the already formed bone tissue. Although the bone formation rate in old rats is rather low, there is some new bone formation which can be observed histologically as a relatively small amount of bone surface showing tetracycline uptake (Larsson 1969 a, b). The amount of glycosaminoglycans emanating from bone tissue laid down during the shorter periods of treatment may be too small to influence the analytical results. Whether this also holds true for longer periods of treatment is more difficult to say. However, it is not unlikely that the major portion of the glycosaminoglycans of compact bone tissue is synthesized during the period of skeletal growth and that the total turnover of glycosaminoglycans in the normal mature skeleton is very low, analogous to that of bone collagen as reported by Aro *et al.* (1965). Therefore, in the present study an effect of the treatment on glycosaminoglycans of bone tissue during formation cannot be fully excluded, especially in the case of steroid administration. On the other hand, the observed similarities of these two types of osteoporosis may support the possibility of a common, more essential factor in the pathogenesis, e.g. enhanced bone resorption because of a need of calcium mobilization. Further studies along these lines, particularly concerning the turnover of bone tissue

In order to facilitate the handling of the obtained CP glycosaminoglycan complexes for subsequent solubilization in a small volume of aqueous propanol, somewhat more bone powder (750 mg) was used than was necessary to run three columns. Smaller amounts can be used the lower limit for only one column is in the range of 50—100 mg of bone powder.

The composition of the bone powder with regard to the relation of mineral/collagen was essentially unchanged in each of the experimental series. This supports the view that the rarefaction of the bones observed in previous studies of the same rats (Larsson 1969 a, b) after longer periods of treatment was, in fact, consistent with osteoporosis. The only exception was the slightly lower mineral content per weight of the bone powders from oophorectomized rats treated with prednisolone for 1—3 weeks. They did not however exhibit the corresponding increase of hydroxyproline which would be expected if an initial phase of osteomalacia was involved. That the lower ash and calcium values mentioned may have originated from a methodological error cannot thus be excluded. Furthermore, no demineralization of bone tissue was found in rabbits treated with dexamethasone for 3 weeks (Vejlens unpublished).

The effect of corticosteroids on the metabolism of glycosaminoglycans has been studied in different tissues both *in vitro* and *in vivo*. Using S^{35} labelled sodium sulphate as the tracer substance Layton (1951 a, b) noted a decrease in the activity of bound sulphate in different tissues after the administration of cortisone. The production of glycosaminoglycans by connective tissue cells in tissue culture becomes decreased in the presence of methylprednisolone (Castor 1962). Rats given cortisone *in vivo* show a decreased uptake of radioactive labelled sulphate and/or acetate by hyaluronate and chondroitin sulphate isolated from the skin (Schiller and Dorfman 1957). The incorporation of S^3 labelled sodium sulphate in the sulphate groups of chondroitin sulphate of calf cartilage becomes decreased both *in vitro* and *in vivo* (Bostrom and Odeblad 1953, Whitehouse and Bostrom 1961). In recent years results have been presented suggesting an inhibitory effect of corticosteroids also on the degradation of glycosaminoglycans in rabbit costal cartilage (Kaplan and Fisher 1964). Low concentrations of hydrocortisone have no significant inhibitory effect on the synthesis of chondroitin sulphate by cartilaginous embryonic chick tibiotarsi in organ culture but have a marked effect on the distribution of the glycosaminoglycan between the tibiotarsus and the culture medium suggesting inhibited degradation (Schryver 1965). As far as the mature bone tissue is concerned nothing has been reported concerning the effect of corticosteroids on the glycosaminoglycans.

In previous studies (Larsson 1969 c, d) data obtained with the aid of Ca^{45} indicated increased mobilization of skeletal calcium for maintenance of the blood calcium level both after combined oophorectomy and prednisolone administration and after prolonged calcium restriction. The results of the present investigation show that during this process of prolonged increased bone resorption the remaining compact bone tissue is quite unchanged with regard to its major components and also to the glycosaminoglycans even after combined oophorectomy and prednisolone treatment for 16 weeks or maintained calcium restriction for up to 1 year. Apart from an unchanged concentration there is no change in the molecular weight distribution of the bone chondroitin sulphate as indicated by unchanged solubility profiles at a similar grade of sulphation.

The lack of an apparent corticosteroid effect on the glycosaminoglycans of mature bone tissue is further supported by results obtained in a short term study of almost fully mature rabbits treated for 3 weeks with other glucocorticosteroids: *e.g.* dexamethasone 0.5 mg/kg body weight daily or cortisone 3 mg/kg daily. The concentrations of total hexosamine, glycosaminoglycans, hydroxyproline and calcium did not differ from those of control animals and neither did the solubility profiles of the CP complexes of chondroitin sulphate (Veplens unpublished).

These findings suggest that the treatments employed did not cause any changes of the glycosaminoglycans in the bone in any case not in the already formed bone tissue. Although the bone formation rate in old rats is rather low there is some new bone formation which can be observed histologically as a relatively small amount of bone surface showing tetracycline uptake (Larsson 1969 a, b). The amount of glycosaminoglycans emanating from bone tissue laid down during the shorter periods of treatment may be too small to influence the analytical results. Whether this also holds true for longer periods of treatment is more difficult to say. However it is not unlikely that the major portion of the glycosaminoglycans of compact bone tissue is synthesized during the period of skeletal growth and that the total turnover of glycosaminoglycans in the normal mature skeleton is very low analogous to that of bone collagen as reported by Aao *et al.* (1965). Therefore in the present study an effect of the treatment on glycosaminoglycans of bone tissue during formation cannot be fully excluded especially in the case of steroid administration. On the other hand the observed similarities of these two types of osteoporosis may support the possibility of a common more essential factor in the pathogenesis *e.g.* enhanced bone resorption because of a need of calcium mobilization. Further studies along these lines particularly concerning the turnover of bone tissue

glycosaminoglycans should provide more knowledge about osteoporotic conditions of these kinds

SUMMARY

The composition of compact bone from adult rats during the development of experimental osteoporosis was studied. Groups of male rats subjected to calcium restriction for various periods up to 12 months and female oophorectomized rats treated with prednisolone for up to 16 weeks were used. Adult, normal rats of corresponding sexes served as controls.

The dried pulverized bone was analysed for contents of mineral (ash calcium), collagen (hydroxyproline), total hexosamine and glycosaminoglycans (as hexosamine of cetylpyridinium precipitable polysaccharides). The relation of mineral/collagen remained mainly unchanged by the treatments, thus confirming that the rarefaction of the bones of animals treated for longer periods noted in previous studies was genuine osteoporosis. The concentrations of total hexosamines and of hexosamines originating from glycosaminoglycans were not affected by the treatments. Of the latter, more than 90 per cent could be accounted for by chondroitin sulphate (see below), and they amounted to less than a third of the total hexosamines.

The glycosaminoglycans of the bone tissue both from normal and experimental animals were isolated and fractionated on the macroscale using the cetylpyridinium precipitation method. The main component was identified as chondroitin 4 sulphate. A smaller part was presumably hyaluronic acid.

Smaller amounts of glycosaminoglycans from bone pooled within experimental groups were also isolated as cetylpyridinium complexes, applied in propanol solution on microcolumns and fractionated. The results indicated that no change in the molecular size pattern of chondroitin sulphate occurred with the different forms of treatment.

GENERAL DISCUSSION

Any attempt to give a survey of the enormous amount of literature concerning clinical osteoporosis meets necessarily with a profusion of contradictory theories of its aetiology (*Dent 1968*). In normal aging there is a gradual steady loss of bone beginning soon after the age of 20 years. This has been considered by some authors to be the main cause of human osteoporosis (*Rose 1967*). However there are most likely additional factors accelerating bone loss and giving rise to symptomatic osteoporosis in juvenile adult and also senile patients (*Dent and Watton 1966*). Further investigations regarding such factors are therefore important both from the clinical and theoretical point of view. In this respect the reaction of the mature bone tissue to nutritional and hormonal disturbances is of special interest. In contrast to the multitude of incoherent data obtained in extensive clinical studies on patients with advanced osteoporosis little information has been provided concerning bone loss in experimental animals. Much of the research and interpretation of data has been influenced by the extensive literature on rickets in rats. However studies of skeletal growth in young animals do not seem to be relevant to the problems associated with the maintenance of the adult skeleton (*Hegsted 1967*). Also concerning induced hormonal disturbances young animals have been studied almost exclusively. Therefore the present investigation was undertaken with the purpose of determining whether or not disturbances induced by a) prolonged calcium restriction and b) oophorectomy combined with prolonged prednisolone administration resulted in changes of the mature bone tissue and calcium metabolism which could be related to the development of osteoporosis according to the definition of *Albright and Reifenstein (1948)*.

A Calcium deficiency

Although restricted calcium intake in adult men results in a negative calcium balance persisting for relatively long periods of time (*Valm 1958*) there is no evidence that a reduced calcium intake can in fact give rise to osteoporosis in humans. It was stated by *Nordin (1960)* that osteoporosis could be induced in adult animals by low calcium diets. However the experimental studies

amounts of vitamin D. It was found in accordance with the results reported by El Maraghi *et al* (1965) that a relatively long period of calcium restriction in adult rats does not result in any notable skeletal changes. However in the present study an evident reduction of bone mass was observed after 14 to 16 weeks of calcium deficiency. These results support those obtained in calcium adaptation studies by Nicolaysen *et al* (1953) and Henry *et al* (1960) that adult rats remain in negative calcium balance for a relatively long period of time after the institution of a low calcium diet. The conclusion by El Maraghi *et al* (1965) that a dietary calcium concentration of 0.11 per cent would probably be adequate for maintenance of the calcium balance in old rats therefore appears to be not valid. Furthermore it was found in the present investigation that on prolonged calcium restriction there was a successive decrease in the ash content of the whole tibia by 6.2 per cent after 16 weeks and 13.3 per cent after 12 months of calcium deficiency. These results are not in agreement with the opinion of Nicolaysen *et al* (1953) that a highly increased efficiency of calcium absorption would compensate for any previous loss in a dietary deprivation period. The findings of the present study are more in line with the observations made by the same authors that in adult rats on a moderately calcium deficient diet there is no such compensatory increase of the calcium absorption.

Corresponding to the reduction of the ash content of the tibia in the present study there was a decrease in the hydroxyproline content of the metacarpal bone. This indicates that there was a concomitant breakdown of minerals and organic bone matrix. Further there was a decrease in the density of the humerus. Thus a widespread loss of bone mass was observed comprising both cancellous bone recorded as a decrease in the number of vertebral bone units and compact bone due to endosteal resorption resulting in the observed reduction in cortical bone thickness.

Histological examination revealed no signs of osteomalacia or osteitis fibrosa. No osteoclasts were observed either in the normal or in the experimental animals. In human osteoporosis bone resorption is known to occur without any obvious formation of osteoclasts (Urist 1958). Since there is no correlation between the number of osteoclasts and the ability of the bone under parathyroid stimulation to supply calcium to the extracellular fluid (Talmage 1967) osteoporosis could possibly develop without any notable formation of osteoclasts. The vertebral bone of the osteoporotic animals was evenly mineralized as observed on micro-radiographs of undecalcified sections and showed no apparent difference from

reported concern almost exclusively young growing animals and have not yielded coherent results

The adult rat is generally considered to be resistant to the development of osteoporosis due to its effective adaptation to a low calcium intake as reported in calcium balance studies (Nicolaysen 1960). However, the variability in calcium absorption studies is considerable (Nicolaysen *et al* 1953) and a prolonged slight loss of calcium from the skeleton would be difficult to determine with calcium balance techniques. The general principle for the adaptation of calcium absorption to reduced calcium intake in old rats is similar to that in aged humans (Nicolaysen *et al* 1953). The adult rat needs 0.5 per cent calcium in the diet for calcium equilibrium (Henry and Kon 1947) and has been reported to remain in negative calcium balance for at least 4 months on restricted calcium intake (Henry *et al* 1960). Therefore the reaction of the skeletal tissue and calcium homeostasis to reduced calcium intake in the adult rat provide special interest with regard to the development of osteoporosis.

The effect of instituting a low calcium diet with normal contents of phosphorus and vitamin D on the bone tissue and calcium metabolism has been studied from different points of view in the present investigation on adult rats. A short preliminary communication of a part of this study was given by Larsson and Sevastikoglou (1966). The studies were planned with the purpose of following the sequence of changes in various parameters which could be related to the development of osteoporosis.

It has been suggested from results of calcium balance studies on old rats that a marked adaptation of calcium absorption will occur only when the animals have suffered a substantial loss of calcium from the skeleton. This distinctly increased efficiency of calcium absorption would compensate fully for any previous loss (Nicolaysen *et al* 1953). However the results obtained in those studies were not quite conclusive. Thus rats fed a low calcium diet *i.e.* with 0.04 per cent calcium showed a successive increase in calcium absorption while rats given a moderately low calcium diet *i.e.* 0.25 per cent did not show this reaction even after several months of calcium underfeeding (Nicolaysen *et al* 1953).

In two year old rats fed for 12 weeks with a diet containing only 0.11 per cent calcium and 0.55 per cent phosphorus little if any effect was found in the weight of ash/cm³ in the whole femur (El Maraghi *et al* 1965). In the present investigation adult rats were maintained on an almost similar low calcium diet, *i.e.* 0.09 per cent calcium and 0.55 per cent phosphorus with adequate

amounts of vitamin D. It was found in accordance with the results reported by El Maraghi *et al* (1965) that a relatively long period of calcium restriction in adult rats does not result in any notable skeletal changes. However in the present study an evident reduction of bone mass was observed after 14 to 16 weeks of calcium deficiency. These results support those obtained in calcium adaptation studies by Nicolaysen *et al* (1953) and Henry *et al* (1960) that adult rats remain in negative calcium balance for a relatively long period of time after the institution of a low calcium diet. The conclusion by El Maraghi *et al* (1965) that a dietary calcium concentration of 0.11 per cent would probably be adequate for maintenance of the calcium balance in old rats therefore appears to be not valid. Furthermore it was found in the present investigation that on prolonged calcium restriction there was a successive decrease in the ash content of the whole tibia by 6.2 per cent after 16 weeks and 13.3 per cent after 12 months of calcium deficiency. These results are not in agreement with the opinion of Nicolaysen *et al* (1953) that a highly increased efficiency of calcium absorption would compensate for any previous loss in a calcium deprivation period. The findings of the present study are more in line with the observations made by the same authors that in adult rats on a moderately calcium deficient diet there is no such compensatory increase of the calcium absorption.

Corresponding to the reduction of the ash content of the tibia in the present study there was a decrease in the hydroxyproline content of the metacarpal bone. This indicates that there was a concomitant breakdown of minerals and organic bone matrix. Further there was a decrease in the density of the humerus. Thus a widespread loss of bone mass was observed comprising both cancellous bone recorded as a decrease in the number of vertebral bone units and compact bone due to endosteal resorption resulting in the observed reduction in cortical bone thickness.

Histological examination revealed no signs of osteomalacia or osteitis fibrosa. No osteoclasts were observed either in the normal or in the experimental animals. In human osteoporosis bone resorption is known to occur without any obvious formation of osteoclasts (Urist 1958). Since there is no correlation between the number of osteoclasts and the ability of the bone under parathyroid stimulation to supply calcium to the extracellular fluid (Talmage 1967) osteoporosis could possibly develop without any notable formation of osteoclasts. The vertebral bone of the osteoporotic animals was evenly mineralized as observed on micro-radiographs of undecalcified sections and showed no apparent difference from

the normal in the amount of bone surface labelled with tetracycline. These observations suggest that a slight continuous loss of bone calcium with a concomitant breakdown of organic matrix occurs on the bone surfaces in the adult rat during prolonged calcium restriction. This long term process results in osteoporosis.

In a unified concept of the pathomechanisms in human osteoporosis the long term process of bone reduction has been related to disturbances in calcium metabolism and the efficiency of calcium homeostasis in maintaining the extra cellular fluid calcium (Heaney 1965). Since there are no data demonstrating such a process it was considered of interest to examine the blood calcium level and the distribution of Ca^{45} between blood and bone during the development of the described calcium deficiency osteoporosis.

It was found in the present investigation that during the development of calcium deficiency osteoporosis the blood calcium values were slightly subnormal initially and also at later periods of time with normal values in between. The hypocalcemia secondary to overfeeding of phosphorus is well known (Liegeois and Derivaux 1951). In the present study the dietary phosphorus was normal according to Henry and Lon (1947) and the hypocalcemia therefore seems to have been caused by the negative calcium balance induced by the lowered calcium intake. The initial transient fall in the blood calcium concentration found in the present investigation corresponds well with that found in short term experiments in healthy adult humans after the institution of a low calcium diet (Nordin 1964, MacFadyen et al 1965). The hypocalcemia of calcium deprivation in humans is believed to be transient and very small changes in blood calcium concentration are considered to be corrected by bone mineral without the intervention of the parathyroid glands due to the existence of genuine steady state between bone mineral and tissue fluid (Nordin et al 1965). During the development of osteoporosis caused by the prolonged negative calcium balance induced in the present investigation slightly subnormal blood calcium values appeared at various periods of time and seemed to be relatively slowly corrected by bone mineral. While under normal circumstances the well documented constancy of blood calcium (Copp et al 1960) is exquisitely well regulated by means of a negative feedback (McLean and Urist 1955), a slightly subnormal blood calcium concentration is seen in prolonged calcium restriction due to the large stresses upon the mechanisms involved in blood calcium regulation. This circumstance does not seem to be in line with the proposal made by Nordin (1961) that primary depression of ionic calcium as produced

by a low calcium diet would cause undersaturation of tissue fluid and immediate shedding of bone mineral with restoration of the blood calcium level. Instead stimulated parathyroid activity might well be involved during the normalization of the blood calcium concentration since a decrease by less than 5 per cent in the blood calcium level may provide an adequate stimulus for increased production of parathyroid hormone (Copp 1963). The possible role played by the parathyroid glands for the development of the osteoporosis described in the present investigation will be the subject of future studies.

The distribution of Ca^{45} between blood and bone at 72 hours after the intraperitoneal administration of the isotope is of special interest with regard to the development of osteoporosis. According to Bauer *et al* (1961) 72 hours after the Ca^{45} injection more than 90 per cent of the observed Ca^{45} activity of the bone has been incorporated into the nonexchangeable fraction of bone salt through accretion. The normal distribution of Ca^{45} rapidly changed upon restriction of the calcium intake in the present study. After only 1 week of calcium deficiency there was an increase by approximately 100 per cent in the blood Ca^{45} activity indicating increased calcium retention. Since the adaptation of the rat to restricted calcium intake is brought about by increased absorption of calcium (Acolaysen *et al* 1953; Henry *et al* 1960) the increased blood Ca^{45} specific activity was due mainly to decreased endogenous Ca^{45} . To a minor degree a decrease in urinary Ca^{45} secondary to the observed slight fall in blood calcium might contribute to the increase in the blood Ca^{45} . Also in human adaptation to reduced calcium intake is effected by more efficient absorption (Malm 1958; Thorangkul *et al* 1959).

After this initial phase there was an increase by approximately 100 per cent in the deposition of Ca^{45} into bone mineral on the 3rd week of continuous calcium restriction and despite a persistent subnormal blood calcium concentration there was a decrease to the normal level of the blood Ca^{45} specific activity. The same distribution of Ca^{45} prevailed also on the 4th and 5th weeks of calcium restriction. The subsequent normalization of the blood calcium concentration after the hypocalcemic period must then have been brought about by increased mobilization of skeletal calcium to the blood. The observed increased deposition of Ca^{45} into bone mineral appears to be secondary to the still more increased mobilization of bone calcium.

After the blood calcium concentration had returned to normal on the 5th week of calcium restriction there was another shift in the distribution of Ca^{45} between blood and bone. Thus on the 8th week of calcium deficiency the Ca^{45}

activity of both blood and bone had reached a level 50 to 60 per cent above that of the normal controls. This distribution of Ca^{45} remained unchanged until the 16th week of maintained calcium restriction and during this period the blood calcium was normal.

These data clearly demonstrate a persistent increase in calcium retention during prolonged negative calcium balance, induced by continuous calcium restriction. In contrast rats fed the test diet enriched with calcium showed significantly decreased Ca^{45} activity of both blood and bone in comparison with the normal controls. The results confirm earlier observations (*Hansard et al* 1951 *Nicolaysen et al* 1953 *Carlsson* 1953 *Henry et al* 1960) that animals accustomed to a high calcium intake must adjust their absorptive mechanism to a lowered supply of calcium.

With continuation of the restricted calcium intake and the development of osteoporosis slightly subnormal blood calcium values were again observed in rats kept on the low calcium diet for 16 weeks and 6 and 7 months. Subsequently between 9 to 12 months of calcium restriction the blood calcium was normal. During the hypocalcemic period another shift in the Ca^{45} distribution indicated that a new dynamic balance was induced in these animals by the prolonged calcium deficiency. Thus, the blood Ca^{45} specific activity showed an increase by 100 to 200 per cent while the Ca^{45} activity of bone was increased by only about 40 per cent. In these animals the contribution of structural changes in cancellous bone to the balance and distribution of calcium must be considered. Due to the loss of cancellous bone and of cortical bone from the endosteal surfaces the amount of bone surface available for intense calcium deposition, i.e. surface accretion is reduced. There was no apparent change in the amount of fluorescent bone surface as observed with the tetracycline labelling method. These circumstances would therefore contribute to the highly increased blood Ca^{45} specific activity observed in these osteoporotic animals. Further acceleration of calcium absorption as suggested by *Nicolaysen et al* (1953) and *Henry et al* (1960) would have a similar effect.

This dynamic sequence of events found in the present investigation demonstrates that with a negative calcium balance induced by prolonged calcium restriction the efficiency of calcium homeostasis in maintaining extracellular fluid calcium is the primary pathomechanism for the development of this type of osteoporosis. During the loss of bone mineral there are shifts in the calcium dynamic balance at different periods of time associated with the occurrence of a slightly subnormal blood calcium concentration.

In clinical osteoporosis the bone accretion rate or mineralization rate is usually reported to be normal (Heaney and Whedon 1958 Fraser et al 1960 Dow and Stanbury 1960 Dymling 1964 Nordin et al 1964) However both a decreased accretion rate (Bauer et al 1957 Eisenberg and Gordon 1961 Lafferty et al 1964) and an increased (Nordin 1959) have also been found. It was therefore considered of interest to estimate the accretion rate in the normal and osteoporotic animals of the present investigation. In 4 groups of rats fed the low calcium diet for 7 8 9 and 10 months the estimated mean accretion rate values for the whole tibia (mg calcium/hour/mg calcium of the tibia) were similar to that of the normal control group. In 2 groups of rats fed the low calcium diet for 6 and 12 months respectively lower values were obtained as compared with that of the control group. These data are in agreement with those reported in human osteoporosis. A normal accretion rate was also reported by Copp and Suiker (1962) for 4 month old rats fed a low calcium diet i.e. 0.037 per cent calcium and 0.43 per cent phosphorus for 6 months. In this latter experiment the effect of the treatment on the skeletal tissue was not studied further. When the calcium accretion rate by bone in osteoporotic individuals is compared with that in normals differences in bone mass must be considered. Furthermore in the present study the higher Ca^{45} activity of bone marrow blood of the osteoporotic animals compared with that of the normal controls also has some influence on the values obtained. These circumstances make it difficult to draw any conclusions regarding the calcium accretion rate by the bone tissue *per se*. The data obtained in the present study only suggest that there is no appreciable difference from the normal in the retention of calcium by the whole tibia and probably by the whole skeleton of the osteoporotic rats. It is pointed out that calcium accretion by bone cannot be equated with bone formation since the amount of tracer localized as diffuse uptake in the bone tissue is too high and variable to allow such a correlation (Rouland 1960).

Lactating female rats have been reported to develop osteoporosis on feeding with a low calcium diet (Tomlin et al 1953 McClendon and Blaustein 1965). Those changes could be reversed by the administration of tricalcium phosphate (McClendon and Blaustein 1965). However the morphological criteria of osteoporosis used i.e. basophilia of the bone trabeculae fibrosis and increased clasmatocytic activity suggest that the bone lesions induced might have been osteitis fibrosa rather than osteoporosis. Kittens fed a low calcium high phosphorus diet develop osteitis fibrosa (Greates et al 1958). This condition is also well known in young cats kept on a low calcium high phosphorus meat

diet (Scott 1957, 1959, Roberts and Scott 1961) and has been shown to be caused by nutritional secondary hyperparathyroidism (Krook *et al* 1963). While young cats develop osteitis fibrosa, adult cats fed a similar low calcium, high phosphorus meat diet i.e. 0.007 per cent calcium and 0.18 per cent phosphorus on a wet weight basis have been reported to develop osteoporosis (Jowsey and Gershon Cohen 1964). In these adult cats there was an increased bone resorption accompanied by an increase in number of newly formed osteones. Contrary to the experience in clinical osteoporosis the reduction in bone mass was reversed by feeding a high calcium diet. In that experiment and in an extended similar study (Jowsey and Raisz 1968) the induced bone changes were related to observed secondary hyperparathyroidism. However, in the latter experiment cats fed the low calcium meat diet for 5 months showed a definite osteomalacia while cats maintained on this diet for 13 months were reported to have developed osteoporosis since the osteoid borders, although highly increased in frequency, were of normal width. The decrease in bone resorption but not in formation observed in such osteoporotic animals after treatment with a high calcium diet for 1 month suggested that the bone changes induced by the low calcium diet could be reversed. This condition differs from that in human osteoporosis by the markedly increased bone formation, osteoporosis in man being characterized by an increase in resorption alone with the bone formation remaining relatively normal. Furthermore young dogs receiving a low calcium diet develop skeletal changes typical of osteitis fibrosa (Campbell and Douglas 1965) as also do mature dogs maintained on a low calcium high phosphorus diet (Saville and Krook 1968). Horses fed either a low calcium high phosphorus diet (Krook and Lowe 1964) or optimal calcium but excessive amounts of phosphorus (Gries 1966) develop osteitis fibrosa due to nutritional secondary hyperparathyroidism. This condition has also been reported in swine fed diets unbalanced in calcium and phosphorus (Brown *et al* 1966). According to Jowsey (1968), growing animals fed a diet low in calcium and high in phosphorus easily develop a frank secondary hyperparathyroidism with depressed serum phosphate and eventually depressed serum calcium osteitis fibrosa and a gross hyperplasia of the parathyroids while in the adult animals the same calcium deficient diet produces no biochemical changes of this kind but symptoms similar to osteoporosis. These findings do not seem to be in accordance with results reported for mature dogs fed a low calcium high phosphorus diet (Saville and Krook 1968). In these animals there was a decrease in gross bone density and histological examination of decalcified bone sections showed the presence of numerous osteoclasts with the appearance of resorption cavities and further osteoblasts

and osteoid tissue covering the surfaces of cancellous bone. Despite the definitely increased amount of osteoid tissue the calcium accretion rate by bone was normal. This might suggest qualitative changes in the bone tissue due to the observed secondary hyperparathyroidism. The opinion has been held that excessive parathyroid hormone prevents the mineralization of osteoid since the glucoproteins do not undergo depolymerization which necessarily must precede mineralization (Krook *et al* 1963). On the other hand it has been proposed that the parathyroid hormone caused depolymerization of the ground substance in bone (Engel 1952, Engel *et al* 1953). Further in accelerated bone resorption as in secondary hyperparathyroidism osteolysis i.e. osteocytic resorption of cells surrounded by matrix containing acid glycosaminoglycans is considered to play an important role (Belanger 1965).

In the processes of calcification and decalcification the protein polysaccharides are probably of importance as controlling factors since at the concentration in which they are found in the vicinity of calcifying sites they would certainly affect the distribution and movement of calcium and phosphate in those regions. The present concepts of the role of the ground substance in calcification has been discussed in a recent extensive review (Bowness 1968). Arguments were presented that acid glycosaminoglycans of ground substance possess properties and occur in situations which would enable them to exert an influence on both the rate and the extent of calcification and decalcification. With regard to human osteoporosis it is of interest that fractions of bone glycosaminoglycans extracted according to Dische *et al* (1958) have been reported to be influenced by both aging and osteoporosis. A versene soluble component, rich in galactosamine was reduced 50 per cent and the galactosamine/gluosamine ratio was decreased in aged or osteoporotic subjects (Cassacio *et al* 1962). Since these changes have been related to the osteoporotic process it was considered of interest to examine the glycosaminoglycans of compact bone tissue during the development of calcium deficiency osteoporosis in the present investigation. From the findings described above changes in the ground substance of bone could be expected in a condition of protracted increased bone resorption. No experimental studies appear to have been reported previously concerning the relationship of the bone glycosaminoglycans to such a long term process of bone reduction. Preliminary reports of this work have been presented by Larsson and Veleus (1967, 1968).

In normal animals and in animals examined at different stages of calcium deficiency in the present study no changes were found in the contents of ash,

calcium or hydroxyproline of the compact bone tissue. Further, there were no changes in the concentrations of total hexosamines and acid glycosaminoglycans. In acutely increased bone resorption induced by administration of parathyroid extract, the mobilization of bone calcium has been related to metabolic changes in organic bone matrix (for references see McLean 1956, Geschwind 1961). No such changes were found during the long term bone reduction in the present investigation. From the finding of a decrease in bone matrix hexosamine in rats treated with parathyroid extract for varying periods of up to 3 days it has been suggested that the dissolution of organic bone matrix and calcium mobilization are closely correlated effects of parathyroid hormone (Johnston *et al* 1961). However, in dogs treated for 3, 4 or 5 days with parathyroid extract no changes have been found in either the concentrations of hexosamines and glycosaminoglycans of the compact bone tissue or the molecular weight distribution of the chondroitin sulphate (Hjertquist and Vejlens 1968). Administration of parathyroid hormone for 3 days to guinea pigs has been reported to cause a significant decrease in the concentration of calcium but no change in concentration of hydroxyproline, DNA or uronic acid of the compact bone. A small but not significant decrease in the bone hexosamine concentration occurred (Bollet *et al* 1963). It was suggested that mobilization of mineral from bone occurs without a concomitant decrease in the concentration of matrix constituents. The discrepancies of the results might be due to various factors such as differences in species, age of the animals, periods of treatment and doses of administered parathyroid extract. During the prolonged process of bone reduction resulting in calcium deficiency osteoporosis in the present investigation there were no changes in the concentrations of minerals, collagen (determined as hydroxyproline), hexosamines or glycosaminoglycans of the compact bone tissue.

It was found in the present investigation that in the compact bone tissue of the adult rat the hexosamines corresponding to acid glycosaminoglycans constituted approximately one third of the total hexosamine concentration. The main component of the acid glycosaminoglycans was found to be chondroitin 4 sulphate which was shown by Meyer *et al* (1956) to be the predominating glycosaminoglycan of bovine compact bone tissue. Apart from an unchanged concentration of the bone chondroitin sulphate there was no change with the development of osteoporosis in its molecular weight distribution as indicated by recorded unchanged solubility profiles and grade of sulphation. This indicates that there was no depolymerization of the glycosaminoglycans of the compact bone tissue during the development of osteoporosis induced by prolonged calcium restriction.

It is concluded that prolonged calcium restriction in adult rats results in a slight continuous loss of bone calcium due to the efficiency of calcium homeostasis in maintaining the blood calcium concentration at the expense of the bone mass from histological microradiographic and tetracycline labelling studies

and biochemical analysis of the remaining compact bone tissue evidence was obtained indicating that the bone changes induced do in fact correspond to osteoporosis according to the definition of Albright and Reifenstein (1948)

B Combined oophorectomy and prednisolone administration

The role of corticosteroid hormones in the homeostasis of the adult skeleton is not clear in contradistinction to their well documented inhibitory effect upon normal skeletal growth and development. Although it has been pointed out in a review by Silberberg and Silberberg in 1956 that adult animals should be used in studies of the relationship between steroid hormones and osteoporosis most available data are still derived from experiments on young animals. The interference of the administered hormones with normal bone growth makes it difficult to make any inferences from such experiments with regard to the maintenance of the mature skeleton and the development of osteoporosis in the adult individual. The osteoporotic bone changes reported in young growing rats after treatment with corticosteroids for various periods of time (Kahn and Skoryna 1959 Storey 1960 Borberg and Lucker 1964) and in young rats first subjected to bilateral adrenalectomy and orchidectomy (Caldwell 1962) seem to be related to the anti-anabolic effect of corticosteroids upon the normal development of the skeleton. Anabolic hormones were found to prevent the osteoporosis reported by Borberg and Lucker (1964) and oestrogens cured the osteoporosis reported by Caldwell (1962) despite continuous cortisone administration. This curative effect might also be due to the fact that in young rats oestrogens inhibit bone resorption (Budy et al 1952 Lindquist 1960). Young mice also have been reported to develop osteoporotic bone changes upon cortisone treatment and these can also be prevented with oestrogens (Glickman and Shklar 1955).

It is well known that corticosteroids induce cytologic changes in the young growing skeleton while in the mature bone this effect is less evident. In young rabbits there is a reduction in number of osteoblasts and new bone formation due to diminished cell division while osteoclast formation and bone resorption continue (Hadfield 1955 Storey 1957 deValderrama and Munuera 1965). This effect on the bone cell populations results in a massive resorption of

calcium or hydroxyproline of the compact bone tissue. Further there were no changes in the concentrations of total hexosamines and acid glycosaminoglycans. In acutely increased bone resorption induced by administration of parathyroid extract, the mobilization of bone calcium has been related to metabolic changes in organic bone matrix (for references see McLean 1956, Geschwind 1961). No such changes were found during the long term bone reduction in the present investigation. From the finding of a decrease in bone matrix hexosamine in rats treated with parathyroid extract for varying periods of up to 3 days it has been suggested that the dissolution of organic bone matrix and calcium mobilization are closely correlated effects of parathyroid hormone (Johnston *et al* 1961). However in dogs treated for 3, 4 or 5 days with parathyroid extract no changes have been found in either the concentrations of hexosamines and glycosaminoglycans of the compact bone tissue or the molecular weight distribution of the chondroitin sulphate (Hjertquist and Vejlens 1968). Administration of parathyroid hormone for 3 days to guinea pigs has been reported to cause a significant decrease in the concentration of calcium but no change in concentration of hydroxyproline, DNA or uronic acid of the compact bone. A small but not significant decrease in the bone hexosamine concentration occurred (Bollet *et al* 1963). It was suggested that mobilization of mineral from bone occurs without a concomitant decrease in the concentration of matrix constituents. The discrepancies of the results might be due to various factors such as differences in species, age of the animals, periods of treatment and doses of administered parathyroid extract. During the prolonged process of bone reduction resulting in calcium deficiency osteoporosis in the present investigation there were no changes in the concentrations of minerals, collagen (determined as hydroxyproline), hexosamines or glycosaminoglycans of the compact bone tissue.

It was found in the present investigation that in the compact bone tissue of the adult rat the hexosamines corresponding to acid glycosaminoglycans constituted approximately one third of the total hexosamine concentration. The main component of the acid glycosaminoglycans was found to be chondroitin 4 sulphate which was shown by Meyer *et al* (1956) to be the predominating glycosaminoglycan of bovine compact bone tissue. Apart from an unchanged concentration of the bone chondroitin sulphate there was no change with the development of osteoporosis in its molecular weight distribution as indicated by recorded unchanged solubility profiles and grade of sulphation. This indicates that there was no depolymerization of the glycosaminoglycans of the compact bone tissue during the development of osteoporosis induced by prolonged calcium restriction.

It is concluded that prolonged calcium restriction in adult rats results in a slight continuous loss of bone calcium due to the efficiency of calcium homeostasis in maintaining the blood calcium concentration at the expense of the bone mass. From histological microradiographic and tetracycline labelling studies and biochemical analysis of the remaining compact bone tissue evidence was obtained indicating that the bone changes induced do in fact correspond to osteoporosis according to the definition of *Albright and Reifenstein (1948)*.

B Combined oophorectomy and prednisolone administration

The role of corticosteroid hormones in the homeostasis of the adult skeleton is not clear in contradistinction to their well documented inhibitory effect upon normal skeletal growth and development. Although it has been pointed out in a review by *Silberberg and Silberberg* in 1956 that adult animals should be used in studies of the relationship between steroid hormones and osteoporosis most available data are still derived from experiments on young animals. The interference of the administered hormones with normal bone growth makes it difficult to make any inferences from such experiments with regard to the maintenance of the mature skeleton and the development of osteoporosis in the adult individual. The osteoporotic bone changes reported in young growing rats after treatment with corticosteroids for various periods of time (*Lahn and Skoryna 1959 Storey 1960 Borberg and Luckner 1964*) and in young rats first subjected to bilateral adrenalectomy and orchidectomy (*Caldwell 1962*) seem to be related to the anti anabolic effect of corticosteroids upon the normal development of the skeleton. Anabolic hormones were found to prevent the osteoporosis reported by *Borberg and Luckner (1964)* and oestrogens cured the osteoporosis reported by *Caldwell (1962)* despite continuous cortisone administration. This curative effect might also be due to the fact that in young rats oestrogens inhibit bone resorption (*Budy et al 1952 Lindquist 1960*). Young mice also have been reported to develop osteoporotic bone changes upon cortisone treatment and these can also be prevented with oestrogens (*Glickman and Shklar 1955*).

It is well known that corticosteroids induce cytologic changes in the young growing skeleton while in the mature bone this effect is less evident. In young rabbits there is a reduction in number of osteoblasts and new bone formation due to diminished cell division while osteoclast formation and bone resorption continue (*Hadfield 1955 Storey 1957 deValderrama and Munuera 1965*). This effect on the bone cell populations results in a massive resorption of

bone in young rabbits while old animals respond only to a slight degree (Storey 1961) Studies in young rats have provided evidence suggesting that in this species the cellular response to excess corticosteroids is dependent also on calcium intake and the ratio of calcium to phosphorus in the diet Thus when the diet contains high, balanced amounts of calcium and phosphorus, cortisone administration results in dense metaphyseal bone due to inhibition of both the formation and resorption processes (Follis 1951 Storey 1960) With a normal decreased or unbalanced Ca/P intake the response of the metaphyseal bone is the same as in rabbits (Sissons and Hadfield 1956 Storey 1960 Simmons and Kunin 1967)

Since bone actively participates in homeostatic processes in the body the well recognized effect of adrenal cortical hormones upon calcium metabolism might also influence the bone tissue In young growing animals the inhibitory effect of corticosteroids on growth makes it difficult to evaluate the hormonal influence on calcium metabolism and bone mineralization *per se* In a recent study on young rats the calcium metabolism was studied with the aid of Ca^{45} and the growth rate was determined by repeated labellings with tetracycline It was found that during treatment with corticosteroids the calcium accretion rate showed a reduction corresponding to the inhibition of growth (Bohr 1968)

It is evident from the findings discussed above that the maturity and age of the skeletal tissue are of decisive importance for the effect exerted by excess corticosteroid hormones In the present investigation one year old rats which had passed the period of active growth were used Histological examination of vertebral bone of the control rats revealed morphological changes which could be attributed to normal chronologic or physiologic aging Morphological changes due to physiologic aging of bone have been described in aged humans (Sherman and Selakovitch 1957) and are considered to be more pronounced in patients with severe osteoporosis (Urist *et al* 1963) In the present study the morphological appearance of the bone tissue was similar in the prednisolone treated oophorectomized rats and the normal controls In the vertebral bone tissue no osteoclasts at all were observed either in the normal controls or in the oophorectomized rats treated with prednisolone for varying periods up to 16 weeks A small amount of bone surface showing tetracycline uptake was the only sign of low osteoblastic activity Despite the time interval of 10 days between the two administered doses, only a narrow fluorescent line was seen in the normal rats A similar low degree of tetracycline labelling was also observed in the oophorectomized prednisolone treated rats

In the present study there was a significant decrease by 6 to 7 per cent in the ash content of the whole tibia after treatment with oophorectomy combined with administration of prednisolone for 14 or 16 weeks. There was a slight but insignificant decrease in the hydroxyproline content of the whole metacarpal bone, the gross bone density of the humerus and the percentage of vertebral bone hits. On direct measurement, a significant reduction was observed in the cortical thickness of the mid shaft of the femur probably caused by increased endosteal bone resorption. On microradiographs of undecalcified vertebral sections the bone tissue was evenly mineralized in both normal and experimental animals. These findings suggest that in adult rats combined treatment with oophorectomy and prednisolone administration for prolonged periods of time i.e. at least 14 or 16 weeks results in moderate osteoporosis.

Being a part of the connective tissue bone is also affected by the influence of steroid hormones on the formation and development of this tissue. The greater effect observed in young growing rats in the experiment by Caldwell (1962) might be due to the well known anti anabolic action of cortisone on collagen synthesis as reported by Smith and Allison (1965) while in the present study this interference would probably be rather small since bone collagen in rats is synthesized predominantly at an early age (Kao *et al* 1965). Besides an inhibitory effect on the synthesis of bone collagen a direct degrading effect upon bone collagen similar to that on dermal collagen as reported by Houck and Patel (1965) and Kowalewski (1966) must be considered. However there are other reports suggesting only an anti anabolic action of corticosteroids on collagen synthesis but no effect on the catabolism of collagen (Kivikko *et al* 1965, Smith and Allison 1965). The metabolism of bone collagen in relation to the development of experimental osteoporosis will be a subject of future study.

In view of the above discussion it is of interest that the significant decrease in ash content of the whole tibia in the groups of oophorectomized rats treated with prednisolone for 14 or 16 weeks corresponds to that previously observed in male rats after specific calcium restriction for the same periods of time. Thus in the former the decrease amounted to 6.1 per cent and in the latter to 6.2 per cent. This suggests that changes in calcium metabolism induced by this hormonal disturbance might be of special interest with regard to the development of this type of osteoporosis. In this respect the effect on the blood calcium level, the distribution of intraperitoneally administered Ca^{45} between blood and bone and on the calcium accretion by bone would provide further

information. A study of these effects has been reported in part previously (Larsson 1968).

It was found in the present investigation that combined treatment with oophorectomy and prednisolone administration resulted in a slight initial fall in the blood calcium concentration followed by a return to normal values corresponding to the observations after the institution of a low calcium diet in adult male rats. Thus, with both these different disturbances slightly subnormal blood calcium values were noted in groups of rats treated for 1, 2, 3 and 4 weeks. Also at later periods of time slightly subnormal blood calcium values were recorded. While no effect of cortisone on the blood calcium level was found in young rats by Williams *et al* (1962) and an increase was observed after prednisolone administration to dogs (Garrett *et al* 1964), there are other reports indicating that cortisone lowers the blood calcium in young rats (Laron *et al* 1958, Simmons and Kinn 1967) and in rabbits (Pincus *et al* 1951). These contradictory results might be due to such factors as the age of the experimental animals, the calcium intake and duration and the dose of corticosteroid hormone administered. From the observation that hydrocortisone reduces the blood calcium in patients with hypoparathyroidism (Leifer and Hollander 1953) and in parathyroidectomized animals of different species (Mirvish and Bosman 1929, Stoerk and Arison 1961) it has been suggested that failure to observe the same effect in normal animals was due to secondary hyperparathyroidism (Stoerk *et al* 1963). From the findings in young rats that the hypocalcemia following parathyroidectomy is aggravated by hydrocortisone and that 3.5 times more parathyroid extract is needed to sustain normal blood calcium concentrations in the presence of hydrocortisone it has been suggested that the development of cortisone osteoporosis might be due to secondary hyperparathyroidism and increased bone resorption (Stoerk *et al* 1963). However, in a recent study of cortisone treated young rats a slight decrease in blood calcium was recorded but there were no morphological signs of increased parathyroid activity (Hansson 1967). Since the animals were fed a high calcium diet it is possible that this prevented the development of secondary hyperparathyroidism. A recent preliminary study of the parathyroids in cortisone treated adult rabbits gave no conclusive results as to the effect of cortisone alone or cortisone plus excess calcium (Adams and Jowsey 1967). Thus, the role played by the parathyroids in the development of cortisone osteoporosis remains to be determined. The effect of the hormonal disturbance induced by combined oophorectomy and prolonged prednisolone administration on the parathyroid function will be a subject of future study.

In the present study there was an increased elimination from the blood of intraperitoneally administered Ca^{45} after oophorectomy combined with prednisolone administration for varying periods of time. Furthermore a change from the normal was observed in the distribution of Ca^{45} between blood and bone examined 72 hours after isotope injection. After an initial phase combined treatment with oophorectomy and prednisolone administration for 4 to 16 weeks resulted in a concomitant decrease in the Ca^{45} activity of blood and bone. These findings indicate that in the adult rat the hormonal disturbance induced by combined oophorectomy and prolonged prednisolone administration results in an increased loss of calcium persisting throughout the period of treatment. The slight decrease observed in the blood calcium concentration seems to be secondary to poor or retarded adaptation to this calcium wasting effect.

Corticosteroid administration has been reported to increase the excretion of injected bone seeking isotopes in young rats (Clark *et al* 1959, Milhaud *et al* 1960, Bohr and Davids 1964, Clark and Smith 1964). In young growing animals this might be due to decreased reabsorption of calcium by the renal tubules as reported by Clark and Roth (1961) but also to an inhibitory effect of the corticosteroids on normal bone growth resulting in decreased bone mineralization as demonstrated by Bohr (1968). The reports regarding the effect of corticosteroids on intestinal calcium absorption in the rat are not fully conclusive. Thus a decreased calcium absorption was reported by Milhaud *et al* (1960) while no effect on the overall gastrointestinal calcium absorption was found by Clark and Smith (1964). In dogs prednisolone increases the amount of intravenously administered Ca^{45} eliminated in the faeces and urine (Collins *et al* 1962) and in humans cortisone and ACTH increase the calcium excretion in both faeces and urine (Luft and Sjogren 1951). The reabsorption of calcium by the renal tubules has been reported to be reduced in humans treated with corticosteroids possibly due to an anti anabolic effect of the hormone on the tubular cells (Laake 1960).

In young growing rats excess corticosteroids have been reported to inhibit the uptake of bone seeking isotopes by bone (Clark *et al* 1959, Bohr and Davids 1964) and it has been suggested that the limiting factor may lie in the synthesis of chondroitin sulphate (Clark *et al* 1959). In the adult fully grown rats used in the present investigation the estimated mean calcium accretion rate for the tibia was found to be increased in the two groups of oophorectomized rats treated with prednisolone for 1 and 2 weeks while in six groups of animals treated for 3 to 12 weeks approximately normal values were found. Two groups of rats treated for 14 and 16 weeks showed fluctuating values. These results

information. A study of these effects has been reported in part previously (Larsson 1968).

It was found in the present investigation that combined treatment with oophorectomy and prednisolone administration resulted in a slight initial fall in the blood calcium concentration followed by a return to normal values corresponding to the observations after the institution of a low calcium diet in adult male rats. Thus with both these different disturbances slightly subnormal blood calcium values were noted in group of rats treated for 1, 2, 3 and 4 weeks. Also at later periods of time slightly subnormal blood calcium values were recorded. While no effect of cortisone on the blood calcium level was found in young rats by Williams *et al* (1962) and an increase was observed after prednisolone administration to dogs (Garrett *et al* 1964) there are other reports indicating that cortisone lowers the blood calcium in young rats (Larson *et al* 1958, Simmons and Kunin 1967) and in rabbits (Pincus *et al* 1951). These contradictory results might be due to such factors as the age of the experimental animals, the calcium intake and duration and the dose of corticosteroid hormone administered. From the observation that hydrocortisone reduces the blood calcium in patients with hypoparathyroidism (Leifer and Hollander 1953) and in parathyroidectomized animals of different species (Mirvish and Bosman 1929, Stoerk and Arison 1961) it has been suggested that failure to observe the same effect in normal animals was due to secondary hyperparathyroidism (Stoerk *et al* 1963). From the findings in young rats that the hypocalcemia following parathyroidectomy is aggravated by hydrocortisone and that 3-7 times more parathyroid extract is needed to sustain normal blood calcium concentrations in the presence of hydrocortisone it has been suggested that the development of cortisone osteoporosis might be due to secondary hyperparathyroidism and increased bone resorption (Stoerk *et al* 1963). However in a recent study of cortisone treated young rats a slight decrease in blood calcium was recorded but there were no morphological signs of increased parathyroid activity (Hansson 1967). Since the animals were fed a high calcium diet it is possible that this prevented the development of secondary hyperparathyroidism. A recent preliminary study of the parathyroids in cortisone treated adult rabbits gave no conclusive results as to the effect of cortisone alone or cortisone plus excess calcium (Adams and Jowsey 1967). Thus the role played by the parathyroids in the development of cortisone osteoporosis remains to be determined. The effect of the hormonal disturbance induced by combined oophorectomy and prolonged prednisolone administration on the parathyroid function will be a subject of future study.

aging and more abruptly with osteoporosis (Cassacio *et al* 1962) The significance of these findings in relation to the osteoporotic process remains to be determined As reported previously in the present investigation neither quantitative nor qualitative changes of the bone glycosaminoglycans were found during the development of calcium deficiency osteoporosis In view of the hormonal influence on the metabolism of glycosaminoglycans in other connective tissues (Dziatkowski 1964 Priest 1967) hormonal disturbances could be expected to influence also the glycosaminoglycans of the bone tissue However no reports appear to have been made previously regarding the effect of excess corticosteroids on the glycosaminoglycans of mature bone tissue

As already mentioned there was a significant decrease in the ash content of the tibia in rats treated by oophorectomy combined with prednisolone administration for 14 or 16 weeks On chemical analyses no significant changes in the concentrations of ash calcium or hydroxyproline in the compact bone tissue were found in these animals These findings indicate that the loss of minerals from the whole bone corresponds to osteoporosis Furthermore no changes were found in the concentrations of hexosamines or acid glycosaminoglycans in the compact bone tissue The main glycosaminoglycan was a sulphated galactosaminoglycan with infrared characteristics compatible with chondroitin 4 sulphate In previous experiments corticosteroids have been reported to decrease the concentration of hexosamines in other connective tissues without reducing the collagen content (Sobel *et al* 1958) However the suggestion of Sobel and Marmorston (1954) that a decrease in bone glycosaminoglycans might precede the events which lead to the development of osteoporosis in Cushing's disease seems to be refuted by the results obtained in the present investigation With regard to the metabolism of acid glycosaminoglycans in other connective tissues there is now good evidence that the turnover of the acid glycosaminoglycans and their corresponding polysaccharide protein complexes is fairly rapid at least in comparison with the turnover of collagen (Bostrom 1968) The turnover rate of glycosaminoglycans is related to the age of the individual and varies in different tissues In the adult rat the biological half life of chondroitin sulphate in skin has been estimated to be 8 to 11 days (Bostrom and Gardell 1953 Schiller *et al* 1956) and in cartilage 16 days (Bostrom and Gardell 1953) The incorporation of S^{35} into the glycosaminoglycan fraction of shaft bones of rats of different ages has been studied by Takemitsu (1961) In rats 7 days old the specific activity of the radioactive sulphur in the glycosaminoglycan fraction reached a peak 18 hours after the intraperitoneal administration of $Na_2S^{35}O_4$ and the half life time was 67 days In older animals there was

indicate that in the adult rat the hormonal disturbance induced by combined oophorectomy and prolonged prednisolone administration causes no apparent decrease in the bone mineralization rate. The findings by *Clark et al* (1959) and *Bohr and Dawids* (1964) are in line with the observation that in growing rats excess corticosteroids reduce the calcium accretion rate in correspondence with the inhibition of growth (*Bohr* 1968). The results of the present study are in agreement with those reported in adult healthy humans (*Gordan and Eisenberg* 1963) and in humans treated with corticosteroids (*Nordin et al* 1963, *Nordin et al* 1964). Normal or even increased bone accretion has been reported in osteoporotic patients treated with corticosteroids and it has been suggested that the eventual decrease in bone mass caused by excess corticosteroids might be the result of accelerated bone resorption (*Eisenberg* 1966). The calcium wasting effect of combined oophorectomy and prednisolone administration in adult rats demonstrated in the present investigation indicates that the considerable loss of bone mineral observed after treatment for 14 or 16 weeks was brought about by increased bone resorption which would mobilize bone calcium for maintenance of the blood calcium concentration. With extension of the periods of prednisolone treatment a more pronounced osteoporosis would develop due to the continuous calcium wasting.

On histological examination of the vertebral bone in the present study areas showing basophilic staining with haematoxylin eosin were observed in the metaphyseal bone trabeculae. In sections stained with azocarmine G these areas exhibited only light or no staining and were found to be located in spaces intervening between parallel fibered bone. The evident metachromasia with toluidine blue at pH 4.4 indicated that these areas of intercellular substance probably consisted of acid glycosaminoglycans extending into the trabecular bone as remnants from the epiphyseal cartilage according to *Dziewiatkowski et al* (1957) and *Campo and Tourtellotte* (1967). There was no change in metachromasia after the combined treatment with oophorectomy and prednisolone administration. From the findings in cortisone treated one year old rats of a decrease in the hexosamine content of the whole femur but no change in the collagen content it has been suggested that a decrease of glycosaminoglycans precedes the events leading to the development of osteoporosis in Cushing's disease (*Sobel and Marmorston* 1954). However this observation may be unspecific with regard to the glycosaminoglycans of the bone tissue itself and no support for this theory is obtained from the findings of the present study.

Changes in bone glycosaminoglycans in fractions of vertebral bone tissue extracted according to *Dische et al* (1958) have been reported in normal human

GENERAL SUMMARY AND CONCLUDING REMARKS

1 The aim of the investigation was to determine in the adult rat whether or not disturbances induced experimentally by a) prolonged calcium restriction and b) oophorectomy combined with prolonged prednisolone administration resulted in changes of the mature bone tissue and calcium metabolism which could be related to the development of osteoporosis according to the definition of *Albright and Reifenstein* (1948). Further the studies were planned with the purpose of following the sequence of changes in various parameters which could be related to the development of the disorder. An attempt was made to investigate the possible relationship of changed bone mass to alterations in calcium metabolism under these two conditions. Further the possible effect of these different disturbances on the compact bone tissue was studied with special regard to the glycosaminoglycans.

2 Introductory remarks are made on certain aspects of clinical osteoporosis with special reference to the pathogenesis.

3 A critical survey is made of the literature concerning experimental osteoporosis induced by calcium deficiency or corticosteroid administration.

4 The effect of prolonged calcium restriction on the skeletal tissue was studied in adult male rats. The ash content of the tibia showed values decreasing significantly with time. After 16 weeks there was a decrease by 6.2 per cent and after 12 months by 13.3 per cent indicating a continuous slight loss of bone minerals throughout the experimental period. The hydroxyproline content of the metacarpal bone showed also a significant decrease indicating a concomitant breakdown of organic bone matrix. Radiographic examination showed reduced cortical thickness of the tubular bones and decreased density of the trabecular pattern in the metaphyseal bone after calcium restriction for 6 months and longer. These animals showed significantly lower values for the femur score and the vertebral bone units than the normal controls. No change in mineralization of the vertebral bone was observed on examination.

a gradual shift until the peak was reached at 48 hours the specific activity of sulphur decreased, and the half life time became shorter. Although the metabolic turnover of the bone glycosaminoglycans *in toto* probably decreases with increasing age the combined treatment with oophorectomy and prednisolone administration for varying periods up to 16 weeks could be expected to have some effect on the formation of the bone glycosaminoglycans in the old rats used in the present study. After corticosteroid treatment a decrease in incorporation of S^{35} sulphate into chondroitin sulphate of bovine cartilage *in vitro* has been reported (Bostrom and Odeblad 1954, Whitehouse and Bostrom 1961). However a possible inhibitory effect on the bone glycosaminoglycans might have been too small to influence the analytical quantitative results obtained in the present investigation. On the other hand diminution of both the formation and breakdown of the chondroitin sulphate caused by the excess corticosteroids as reported by Schiller and Dorfman (1957) in a study on rat skin, is also possible. From the findings of an increase of hyaluronate in the vitreous humor and an increase of keratan sulphate in costal cartilage of rabbits treated with prednisolone it has been suggested that corticosteroids have an overall inhibitory effect on the degradation of these glycosaminoglycans (Kaplan and Fisher 1964). A similar effect has also been reported in a study on the synthesis of chondroitin sulphate by cartilaginous embryonic chick tibiotarsi in organ culture (Schryver 1965).

Apart from an unchanged concentration there was no alteration in the molecular weight distribution of the bone chondroitin sulphate as indicated by unchanged solubility profiles and sulphation grade, after combined treatment with oophorectomy and prednisolone administration in the present study. This indicates that there was no depolymerization of the glycosaminoglycans of the compact bone tissue during the development of the osteoporosis induced by this hormonal disturbance.

To summarize in the adult rat both prolonged calcium restriction and hormonal disturbance induced by combined oophorectomy and prolonged prednisolone administration lead to a significant reduction of the skeletal tissue fulfilling the criteria of osteoporosis given by Albright and Reifenstein (1948). During this prolonged process of increased bone resorption changes in calcium metabolism and the efficiency of calcium homeostasis in maintaining extracellular fluid calcium appear to constitute the primary pathomechanism for the development of the disorder. Neither quantitative nor qualitative changes were found in the glycosaminoglycans of the remaining compact bone tissue during this long term process of increased bone resorption.

a gradual shift until the peak was reached at 48 hours the specific activity of sulphur decreased and the half life time became shorter. Although the metabolic turnover of the bone glycosaminoglycans *in toto* probably decreases with increasing age, the combined treatment with oophorectomy and prednisolone administration for varying periods up to 16 weeks could be expected to have some effect on the formation of the bone glycosaminoglycans in the old rats used in the present study. After corticosteroid treatment a decrease in incorporation of S^{35} sulphate into chondroitin sulphate of bovine cartilage *in vitro* has been reported (Bostrom and Odeblad 1954, Whitehouse and Bostrom 1961). However, a possible inhibitory effect on the bone glycosaminoglycans might have been too small to influence the analytical quantitative results obtained in the present investigation. On the other hand diminution of both the formation and breakdown of the chondroitin sulphate caused by the excess corticosteroids as reported by Schiller and Dorfman (1957) in a study on rat skin, is also possible. From the findings of an increase of hyaluronate in the vitreous humor and an increase of keratan sulphate in costal cartilage of rabbits treated with prednisolone it has been suggested that corticosteroids have an overall inhibitory effect on the degradation of these glycosaminoglycans (Kaplan and Fisher 1964). A similar effect has also been reported in a study on the synthesis of chondroitin sulphate by cartilaginous embryonic chick tibiotarsi in organ culture (Schryver 1965).

Apart from an unchanged concentration there was no alteration in the molecular weight distribution of the bone chondroitin sulphate as indicated by unchanged solubility profiles and sulphation grade after combined treatment with oophorectomy and prednisolone administration in the present study. This indicates that there was no depolymerization of the glycosaminoglycans of the compact bone tissue during the development of the osteoporosis induced by this hormonal disturbance.

To summarize in the adult rat both prolonged calcium restriction and hormonal disturbance induced by combined oophorectomy and prolonged prednisolone administration lead to a significant reduction of the skeletal tissue fulfilling the criteria of osteoporosis given by Albright and Reifenstein (1948). During this prolonged process of increased bone resorption changes in calcium metabolism and the efficiency of calcium homeostasis in maintaining extracellular fluid calcium appear to constitute the primary pathomechanism for the development of the disorder. Neither quantitative nor qualitative changes were found in the glycosaminoglycans of the remaining compact bone tissue during this long term process of increased bone resorption.

6 The composition of compact bone from adult rats during the development of calcium deficiency osteoporosis was studied. The glycosaminoglycans were analysed using the cetylpyridinium precipitation method. No significant changes were recorded in the concentrations of ash, calcium, hydroxyproline, total hexosamines or hexosamines originating from the glycosaminoglycans. The unchanged relation of muretal/vollag confirmed that the induced bone rarefaction was genuine osteoporosis according to the definition of Albright and Reifenstein (1948). The main glycosaminoglycan was chondroitin 4 sulphate and a smaller part presumably hyaluronic acid. The unchanged solubility properties of the chondroitin sulphate—cetylpyridinium complexes and unchanged sulphation grade indicated that no change in the molecular size pattern of chondroitin sulphate occurred during the development of the osteoporosis. Of the hexosamines originating from glycosaminoglycans more than 90 per cent could be accounted for by chondroitin sulphate and they amounted to less than a third of the total hexosamines.

7 The effect of combined oophorectomy and prolonged prednisolone administration on the skeletal tissue was studied in adult rats. The excess of corticosteroids caused considerable depletion of adipose and muscle tissues and significant atrophy of the adrenal cortex (zona fasciculata). During the observation period of 16 weeks no radiographic signs of osteoporosis were seen. A significant reduction by 6.1 per cent in the ash content of the tibia was recorded after 14 and 16 weeks of treatment. The "femur score" showed significantly decreased values while there was only a slight though not significant decrease in the percentage of vertebral bone. Both the hydroxyproline content of metacarpal bone and the density of the humerus. Microradiographic examination of undecalcified vertebral bone sections showed no changes in degree of mineralization. Only a small amount of bone surface showing tetracycline labelling was observed both in normal and experimental animals. Histological examination of decalcified sections of vertebral bone from normal and experimental animals showed morphological changes which could be attributed to physiologic aging of bone. In the metaphyseal bone of the vertebrae areas were observed which stained metachromatically with toluidine blue at pH 4.4. No change in metachromasia was observed in oophorectomized rats treated with prednisolone for different periods of time.

8 The effect of combined oophorectomy and prolonged prednisolone administration on the blood calcium level and the distribution of Ca^{45} between

of microradiographs of undecalcified sections Tetracycline fluorescent micrographs showed no difference from the normal These findings indicate that the rarefaction of bone represented osteoporosis No osteoclasts were observed in normal or experimental rats In the metaphyseal bone, areas were observed which were metachromatic with toluidine blue at pH 4.4 No change in metachromasia was observed in osteoporotic animals Rats fed the test diet enriched with calcium for 16 weeks showed a tendency to increased ash content, decreased hydroxyproline content and increased density of whole bones compared with normal controls which might suggest a possible increase in degree of calcification

5 The effect of prolonged calcium restriction on the blood calcium level and the distribution of Ca^{45} between blood and bone was studied in adult male rats The blood calcium was slightly subnormal 1 to 4 weeks after commencement of calcium restriction The blood Ca^{45} specific activity 72 hours after the isotope injection showed an increase by 100 per cent after 1 week of calcium restriction, indicating increased calcium retention Animals treated for 3 or 4 weeks showed similar values to the normal controls but increased deposition of Ca^{45} into the skeleton by 100 per cent despite subnormal blood calcium On the 8th to 14th week of calcium deficiency normal blood calcium values and increased Ca^{45} activity in blood and bone by 50 to 60 per cent were recorded indicating continued increase in the retention of calcium Rats treated for 4 to 7 months showed subnormal blood calcium while in animals fed the diet for 8 to 12 months normal values were found Osteoporotic animals kept on the low calcium diet for 6 to 12 months showed highly increased blood Ca^{45} activity by approximately 200 per cent while the uptake of Ca^{45} by bone was increased by 40 per cent In animals fed the diet enriched with calcium the blood Ca^{45} activity was 40 per cent and bone Ca^{45} activity 60 per cent lower than in controls indicating decreased retention of calcium The mean calcium accretion rate for the tibia (mg calcium/hour/mg calcium of the tibia) was decreased in rats fed the low calcium diet for 6 and 12 months while rats treated for 7, 8, 9 and 10 months showed approximately the same values as the control group From the Ca^{45} data obtained it was deduced that the maintenance of the blood calcium level was brought about by increased mobilization of skeletal calcium to the blood During the loss of bone minerals there were shifts in the calcium dynamic balance at different periods of time associated with the occurrence of a slightly subnormal blood calcium concentration

so that observed after pure calcium restriction for the same periods of time. The calcium wasting effect of this hormonal disturbance observed with the aid of Ca^{45} and the mainly unchanged calcium accretion rate by the bone indicate that the loss of bone minerals was due to increased bone resorption. This seems to be the essential factor in the pathogenesis of this type of osteoporosis which is further supported by the absence of quantitative or qualitative changes in the bone glycosaminoglycans.

11 The essential features of the investigation are summarized in the general discussion. The results are discussed in relation to reported contradictory results of animal experiments. The importance of calcium homeostasis in the pathogenesis of osteoporosis is pointed out.

blood and bone was studied in adult rats. The blood calcium showed subnormal values in rats treated for 1 to 4 weeks while normal values were recorded after 5 weeks. Slightly subnormal values were observed in rats treated for 8 to 14 weeks and finally, normal values after 16 weeks. The rate of elimination of intraperitoneally administered Ca^{45} from the blood was increased in all experimental groups compared with that of the normal control group. Rats treated for 4 to 16 weeks showed consistently decreased values for both the blood and bone Ca^4 activity recorded 72 hours after the isotope injection. The uptake of Ca^{45} by compact bone amounted to less than one fifth of that of the whole tibia and showed also a decrease in rats treated for 4 to 16 weeks. The mean calcium accretion rate of the tibia (mg calcium/hour/mg calcium of the tibia) was found to be increased in the two groups of oophorectomized rats treated with prednisolone for 1 and 2 weeks while in six groups of animals treated for 3 to 12 weeks approximately normal values were found. Two groups of rats treated for 14 and 16 weeks showed fluctuating values. It was deduced from the Ca^{45} data obtained that the blood calcium was sustained by increased mobilization of skeletal calcium resulting in the loss of bone minerals observed in a previous study.

9 The composition of compact bone was studied in normal adult rats and oophorectomized rats treated with prednisolone for varying periods up to 16 weeks. While in previous studies a significant reduction by 6 to 7 per cent in the mineral content of the whole tibia had been found in rats treated for 14 or 16 weeks there was no change in the relation of mineral/collagen in the compact bone of these animals thus confirming that the bone changes noted represented osteoporosis. The concentrations of total hexosamines and of hexosamines originating from glycosaminoglycans were not affected by the combined treatment with oophorectomy and prednisolone administration. Of the hexosamines emanating from glycosaminoglycans more than 90 per cent could be accounted for by chondroitin sulphate and they amounted to less than a third of the total hexosamines. The main glycosaminoglycan was identified as chondroitin 4 sulphate. A smaller part was presumably hyaluronic acid. Results of microfractionation studies of glycosaminoglycan complexes with cetylpyridinium indicated that no change in the molecular size pattern of chondroitin sulphate occurred with the treatment.

10 The hormonal disturbance induced by combined oophorectomy and prednisolone administration resulted in a loss of bone minerals corresponding

as that observed after pure calcium restriction for the same periods of time. The calcium wasting effect of this hormonal disturbance observed with the aid of Ca^{45} and the mainly unchanged calcium accretion rate by the bone indicate that the loss of bone minerals was due to increased bone resorption. This seems to be the essential factor in the pathogenesis of this type of osteoporosis which is further supported by the absence of quantitative or qualitative changes in the bone glycosaminoglycans.

11 The essential features of the investigation are summarized in the general discussion. The results are discussed in relation to reported contradictory results of animal experiments. The importance of calcium homeostasis in the pathogenesis of osteoporosis is pointed out.

I INTRODUCTION

A THE FROZEN SHOULDER

DUPLAY in 1872 described a condition: *peri arthrite scapulo humérale*, which differed from arthritis in its symptoms and clinical course

He also suggested manipulation of the shoulder joint under general anaesthesia as a treatment for the restricted mobility in this disorder

The true nature of this condition has been discussed ever since DUPLAY himself believed that a subacromial bursitis was the basic cause of the pain and dysfunction. However already KLAPP (1916) and KIEDEL (1916) believed that the joint capsule was affected and in consequence PARR (1931) tried to accomplish a distension of the retracted capsular tissue by intraarticular injections

CODMAN (1934) pointed out that stiffness and pain in the shoulder could occur without noticeable exogenous influences and he separated this condition from the heterogenous group referred to as *periarthritis* of the shoulder. He termed the condition "frozen shoulder" an expression which later has been generally accepted and used synonymously with *humero scapular periarthritis in a restricted state*.

CODMAN was of the opinion that the frozen shoulder was caused by tendinitis in the short rotators. Several investigators have related the condition to changes in various periarthicular structures (BOSWORTH 1940, LIPPMAAN 1943, MOSELEY 1943, DEPALMA 1952, McLAUGHLIN 1961, LIDSTROM 1963).

However other investigators (NEVIASER 1943, YOUNG and PEARSON 1952, QUIGLEY 1956, HARMON 1958, DE SÈZE et al 1960, 1961) favoured the opinion that the joint capsule was the site of the basic pathological changes in frozen shoulders.

I INTRODUCTION

A THE FROZEN SHOULDER

DUPLAY in 1872 described a condition *peri arthrite scapulo humerale* which differed from arthritis in its symptoms and clinical course

He also suggested manipulation of the shoulder joint under general anaesthetic as a treatment for the restricted mobility in this disorder

The true nature of this condition has been discussed ever since DUPLAY himself believed that a subacromial bursitis was the basic cause of the pain and dysfunction However already KLAPP (1916) and RIEDEL (1916) believed that the joint capsule was affected and in consequence PATER (1931) tried to accomplish a distension of the retracted capsular tissue by intraarticular injections

CODMAN (1934) pointed out that stiffness and pain in the shoulder could occur without noticeable exogenous influences and he separated this condition from the heterogeneous group referred to as *periarthritides* of the shoulder He termed the condition "frozen shoulder" an expression which later has been generally accepted and used synonymously with *humero scapular periarthritides* in a restricted sense

CODMAN was of the opinion that the frozen shoulder was caused by tendinitis in the short rotators Several investigators have related the condition to changes in various periarticular structures (BOSWORTH 1940, LIPPMAN 1943 MOSELEY 1945 DePALMA 1952, McLAUGHLIN 1961 LIMSTROM 1963)

However other investigators (NEVIASER 1945 YOUNG and PEARSON 1952 QUICKLEY 1956 HARMON 1958 DE SÈZE et al 1960 1961) favoured the opinion that the joint capsule was the site of the basic pathological changes in frozen shoulders

Attempts have been made to relate the disease to various circumstances such as inactivity, strain and pre existing shoulder affection. The importance of the latter was studied by PASILA (1965). Examining cases of periarthritis of the shoulder, "tendinitis" without restricted mobility, he did not find that this condition during the course of the disease developed into frozen shoulder.

The therapy of frozen shoulders has been based on the varying opinions of the basic cause of the disease. It is rather difficult to draw any final conclusions from the literature. One reason is the indistinct definitions. The lump diagnosis "periarthritis" has been used in a wide as well as in a limited sense and this has greatly contributed to the confusion. It seems important to restrict the diagnosis of frozen shoulders to cases with a distinct limitation of mobility in the humero scapular joint. It is also necessary to separate cases with known exogenous causes or pre existing injuries from cases without or with a doubtful history of exogenous influence.

B PURPOSE

The purpose of the present investigation was to collect further information from a series of individuals suffering from the frozen shoulder syndrome. Except for clinical observations of these cases the following methods were applied:

- 1 Manipulation under general anaesthesia
- 2 Arthrography
- 3 Measurements of the joint volume
- 4 Surgical exposure
- 5 Histological examination
- 6 Chemical analysis
- 7 In vivo bone densitometry
- 8 Mineral tracer studies

The emphasis in the study has been on the examination and presentation of clinical variables.

COMMENT

PAYR (1931) noticed a reflux when he injected periarthritic joints. The volume in normal shoulder joints has been estimated to 16–35 cc (HARMON 1958, DE SÈZE 1961 and REEVES 1966). It has previously been stated that the joint capacity is reduced in F S (NELSON 1952, HARMON 1958). DE SÈZE et al (1966) found volumes as small as 5–6 cc in F S. VIALLA et al (1964) found higher intraarticular pressures for a given injected volume in F S as compared to normal joints. Both variables, pressure and volume, reflect the same condition: capsular retraction.

In the present study it has been demonstrated that the volume of the joint is related to the severity of the disease. The finding suggests volumetry as a complementary diagnostic test of capsular retraction.

VII OPERATIVE FINDINGS

Twenty shoulders were exposed surgically through an anterior incision before the manipulation, 15 were Primary and 5 Secondary I S In 6 shoulders the subscapular tendon was dislocated and the capsule incised In these cases the incision considerably released the humero scapular mobility The manipulation was then completed in the usual way After the brisement, the joint surface of the head of the humerus could be felt through the ruptured capsule

In conjunction with the surgical exposure of these joints the following observations were made

- a) Periarticular inflammatory changes, especially in the insertion of the rotator cuff on the greater tubercle
- b) Thickening of the joint capsule
- c) No intraarticular adhesions
- d) No signs of rupture of the subscapular tendon during the manipulation

The surgical exposure also provided material for the chemical analysis and the histological examinations described later

VIII HISTOLOGICAL EXAMINATION OF THE JOINT CAPSULE

A LIGHT MICROSCOPY

From 14 F S 12 Primary and 2 Secondary, in which the shoulder was exposed surgically biopsies were taken from the lower anterior portion of the joint capsule. The samples were embedded in paraffin sectioned and stained with haematoxylin eosin, with toluidine and according to VAN GIESON.

Samples were also collected from the same part of the shoulder joint in individuals with a normal range of motion who were operated on for various reasons mostly habitual dislocation of the shoulder.

In the reference cases 9 S and D 1 (Table V) the biopsies were taken within a month after traumatic lesions, which however were not associated with a decreased range of motion (rotator cuff rupture and traumatic shoulder dislocation respectively).

The samples were studied with respect to thickening and vascularity of the synovial lining and denseness vascularity and hyperplasia of the adjacent fibrous layer. The morphological ranking of the sections was done by a pathologist who did not know their origin.¹

The results of the histological study are shown in Table V. In general, the connective tissue in the reference shoulders was organized in bundles or groups of bundles with comparatively few fibrocytes. In sections from joint capsules of F S the fibrous tissue appeared more compact or dense (referred to as denseness in the Table). In addition to the impression of denseness there were more cells mostly fibroblasts and sometimes increased vascularity (Appendix A). The synovial lining was largely unchanged except for the fact that in F S capillaries were observed more often. No difference between F S and normal could be demonstrated in the metachromatic staining of the toluidine treated sections.

The general impression of the morphological changes in the joint capsule in F S was that of *fibrosis and fibroplasia*.

COMMENT

It was not possible to collect reference cases of the appropriate age and sex distribution. There is however no evidence that changes of the type found in the F S reflect age and sex only.

¹ J. G. Norden, M.D., Department of Pathology General Hospital Malmö

NEVIASER (1945) found signs of chronic inflammation and fibrosis in the sub synovial layers of FS, "capsulitis" DePALMA (1952) found histological evidence of a low grade chronic inflammatory process not only in the fibrous joint capsule but also in various periarticular structures

The present study supports these findings but no significant amount of inflammatory cells was found The morphology was similar to that of DUPUYTREN'S contracture (NORDEN 1969) ASK UPMARK (1944) stated that

¹ Secondary frozen shoulders

such palmar infiltations were common in cardiosclerotic patients with shoulder disorders. DUPUYTREN'S contracture was present in 25 % of SCHAEFER (1936) cases of periarthritis of the shoulder. KLAMM (1962), however, could not demonstrate any such relationship.

B. ELECTRON MICROSCOPY

In order to obtain information concerning the individual fibrils including their periodicity, the ultrastructure of the joint capsule was studied in samples from 4 normal shoulders and 3 Primary FS.

The samples were prefixed in 2.5 % glutaraldehyde in phosphate buffer pH 7.2, fixed in 1–2 % osmium tetroxide (MILLON 1962) and embedded in Vestopal W. Sections were made with an LKB microtome Ultratome and examined in a Hitachi HS 7S electron microscope. Some sections were stained in lead citrate (REYNOLDS 1963).¹

The sections were studied and photographed with special reference to the appearance and arrangement of the collagen bundles and individual fibrils. The general impression in FS was that of a more compact arrangement of the collagen fibres; there were also as was expected from light microcopy, more cellular elements present. Between normal shoulders and FS there was no indication of differences in structure or periodicity of the fibrils (Appendix 1). The variation of collagen appearance was not greater between pathological and normal sections than between sections from the same shoulder.

COMMENT

The character of the capsular changes in the FS leads to the suspicion that the properties of collagen in the tissue are changed, and that the FS is a symptom of disease in the collagen itself. Electron microcopy of capsules from a limited number of shoulders did not indicate structural changes.

¹ The preparation was supervised and the photographs examined by C. A. Mecklenburg, M.D., Department of Zoology, University of Lund, Lund.

NEVIASER (1945) found signs of chronic inflammation and fibrosis in the sub synovial layers of F S, "capsulitis" DEPALMA (1952) found histological evidence of a low grade chronic inflammatory process not only in the fibrous joint capsule but also in various periarticular structures

The present study supports these findings but no significant amount of inflammatory cells was found The morphology was similar to that of DUPUYTREN'S contracture (NORDEN 1969) ASK UPMARK (1944) stated that

IX ANALYSIS OF GLYCOSAMINOGLYCANS¹ IN THE JOINT CAPSULE

A MATERIAL

From 14 surgically exposed F S, two of which were secondary, biopsy specimens were taken from the joint capsule for chemical analysis (LUND BERG 1969). Similarly biopsies were taken from 13 cases with a free range of motion, who were operated on, mostly because of habitual shoulder dislocation. Differences in age and sex distribution between the two groups existed to the same extent as in the histological study and for the same reasons.

B CHEMICAL ANALYSIS²

The glycosaminoglycans were liberated from the capsular tissue by papain digestion according to SCOTT (1960).

The glycoproteins were separated from the glycosaminoglycans by chromatography of 50 μ l of the digestion mixture (corresponding to about 2.5 mg dry weight of the capsule) on ECTEO LA columns as described by RINGERTZ and REICHARD (1960). By this procedure the glycoproteins were recovered after elution with water and 0.02 M HCl, the unsulfated glycosaminoglycans with 0.5 M NaCl and the sulfated with 6 M HCl (Table VI 1).

For further determination of the glycosaminoglycans they were precipitated as water insoluble cetylpyridinium complexes on columns of powdered cellulose and fractionated as described by ANTONIOUDES *et al* (1964) by washing with salt solutions of increasing concentrations (Table VI 2). To each micro cellulose column was added 50 μ l of a digest equivalent to approximately 2.5 mg dry capsule.

Larger amounts of material, corresponding to approximately 25 mg of dry tissue weight, were fractionated on cetylpyridinium chloride (CPC) cellulose microcolumns according to THUNELI's (1967) modification. With this method the glycosaminoglycans were precipitated with 1 % aqueous CPC and fractionated before and after treatment with testicular hyaluronidase (Table VI 3).

¹ Equivalent to mucopolysaccharides according to the terminology of BALAZS and JEANLOZ (1965).

² The work was carried out under supervision of S. Gardell M.D. at the Department of Physiological Chemistry, University of Lund, Lund.

C RESULTS

The available amount of material was too small to permit an identification of the glycosaminoglycans in the synovial tissue from shoulder joints. However, on the basis of results obtained from studies on the glycosaminoglycans in human knee joint capsules (HEINEGARD et al 1968) it was possible to determine the origin of the hexosamines in the present study.

The results presented in Table VI imply, regardless of method, an increased total amount of hexosamines in the synovial tissue of the FS as compared to normal. The increase was confined to the sulfated glycosaminoglycans. There was a significant reduction of the glycoprotein content in the FS joint capsule as evaluated from the decreased amount of hexosamine recovered after elution with water and 0.02 M HCl of the digested material on ELTEOLA columns. The hyaluronic acid exclusively present in the 0.3 M NaCl fraction (HEINEGARD et al 1968) was also reduced (Table VI, 3). Concerning the sulfated glycosaminoglycans the same study indicated that the 0.3 M $MgCl_2$ fraction corresponded to heparan sulfate while the chondroitin 6 sulfate and the dermatan sulfate were recovered in the subsequent fractions.

The values of the latter fractions were higher in samples from the FS. There were no differences in the degree of dermatan sulfate hybridization between frozen and normal shoulders as indicated by the effect of hyaluronidase treatment (FRANSSON and RÖDEN 1967). This analysis revealed that dermatan sulfate is a major component of the glycosaminoglycans in joint capsules.

COMMENT

Some parallels may be drawn between the composition of granulation tissue and synovial tissue of FS. SYLVÉN (1941) found metachromasia in regenerating tissue of healing wounds. VINOGRADOV (1966) demonstrated that an increase of glycosaminoglycans was associated with intense proliferation of fibroblasts. Hyperplasia of the fibroblasts and an increase of the glycosaminoglycans are characteristic for the joint capsules of FS. BLRENSEN and DALFERES (1960) found that the content of chondroitin sulfate in granulation tissue increased more rapidly than that of hyaluronic acid. In the present study these components were changed in the same direction. It may be suggested that the changes in the glycosaminoglycans are characteristic for a repair reaction. AKESON et al (1967) found in experimentally immobilized knees of dogs a decrease of the contents of hyaluronic acid and chondroitin sulfate in the periaricular connective tissue. Therefore the findings in the present study may reflect not a secondary effect of immobilization but rather the pathogenesis of the condition.

LOCAL CHANGES IN BONE METABOLISM

1 BONE DENSITOMETRY

1 Material and Methods

In 40 cases of Primary FS 23 women and 17 men the bone mineral mass of the head of the humerus was evaluated. In addition 10 men and 10 women randomly selected among persons without any history of injury to the upper limb, were measured. The method which has been described in detail elsewhere (NILSSON 1966 LUNDBERG and NILSSON 1968) made use of the radiation from a source of Americium 241. The attenuation of a photon beam from the source was measured as the beam passed through the head of the humerus. The soft tissue was accounted for by the use of a water phantom of the same thickness as the bone and soft tissue interposed in the path way of the beam.

All individuals included in this study were right handed. There was no preponderance for left or right in this group of Primary FS. Their average age is given in figure 12.

2 Results

In the reference cases the head of the left humerus contained less mineral expressed as the thickness in the path way of the beam (g/cm^2) than did the right. This difference was however significant only in women.

as a function of time
after recovery

In the cases of F S there was a significant decrease of bone mass in the affected side as compared to the unaffected one. The average difference amounted to about 50 % of the mineral content of the unaffected side (Fig 12). There was no evidence that the degree of osteopenia associated with F S was age dependant (Fig 13) nor that it increased with an extended duration of the condition (Fig 14). There was no evidence of restoration of the mineral mass with time (Fig 15).

B TURNOVER OF ^{85}Sr

I Material and Methods

Fifteen cases suffering from unilateral Primary F S: 7 men and 8 women, were included in this study. Another 6 unilateral but recovered cases: 2 men and 4 women were included. They had recovered from their F S 9 months to 4 years before the measurement and had regained full range of motion and normal function of their shoulder joints. For reference 8 individuals: 3 men and 5 women without history or clinical signs of symptoms of shoulder disease or injury were measured. Another 6 references: 5 men and 1 woman with pain in one shoulder for 3 months or more but without decreased range of motion were measured. The age of references and F S cases was about the same.

All the patients were injected intravenously with $50\text{ }\mu\text{Ci}$ of $^{85}\text{Sr}(\text{NO}_3)_2$. Two weeks later the activity was recorded over the shoulder and over the elbow using a lead shielded scintillation detector with a 12° wide angle collimator (diameter of outer aperture 63 mm). The geometry of the detector in relation to the shoulder joint is shown in Figure 16. The uptake in the elbow was measured with the detector in skin contact facing the lateral aspect of the joint.

For evaluation of the changes in uptake a ratio was formed between the background corrected count rates obtained from the affected and the unaffected limbs respectively (Fig 17).

2 Results

The uptake in Primary F S was significantly increased when compared to the reference cases. In cases who had restored their range of motion the uptake was significantly decreased as compared to the current cases (Tab

le VII) In painful shoulders without decreased range of motion the uptake did not exceed that of the other reference group

There was also some indication of increased uptake in the elbow region of the FS affected limb. Again the uptake in the restored cases was significantly less (Table VIII)

There was no difference between men and women in either group

Fig 16

The detector positioned over the shoulder. The isoresponse areas shown in relation to the upper end of the humerus

COMMENT

Within a few months after a tibial shaft fracture a loss of mineral in the knee region of about 25 % has been demonstrated (NILSSON 1966). At the same time the uptake of ^{85}Sr in the same area is usually about quadrupled (WENDEBERG 1961). These findings indicate a primary loss of bone due to resorption followed by a response of increased bone formation as evaluated from the ^{85}Sr uptake. In the present study the loss of bone exceeds that found in the knee region following fracture and is much greater than could be expected from immobilization so far nobody has been able to demonstrate a convincing local osteopenia in man as a result of immobilization only. A joint affection such as a tear of the semilunar cartilage results in a loss of no more than 10 % of the bone mass (NILSSON and WESTLUND 1968). The loss of bone associated with FS, 50 % is therefore remarkably large.

If the continuous loss of bone is taken into account, the initial uptake

B STATISTICAL METHODS

For comparison of frequencies the method of Chi square with Yates correction was used

For comparison between sets of numerical data and between paired data the method of *t* test was used differences in variance in the sets being taken into consideration Skewed distributions were also compared using the geometric means and standard deviations

If interaction from variables other than the tested could be expected, analysis of covariance was used with the interacting variable as the co variant factor even if no significant correlation was found between the two variables

Correlation was calculated as the linear correlation coefficient

Differences and correlations have been referred to as significant when the level of probability was less than 5 %

The central tendency and the scatter of the data were represented as arithmetic Average \pm Standard Deviation unless otherwise stated.

B STATISTICAL METHODS

For comparison of frequencies the χ^2 test and continuity correction was used.

For comparison between sets of numerical measurements the method of t test was used, differences in variance were taken into consideration. Skewed distributions were analysed by the geometric means and standard deviation.

If interaction from variables other than sex was suspected analysis of covariance was used with the treatment as the variant factor even if no significant interaction was found between two variables.

Correlation was calculated as the Pearson product moment correlation coefficient.

Differences and correlations have been tested at the 5% level, the level of probability was less than 0.05.

The central tendency and the scatter of the data were measured by arithmetic Average and Standard Deviation.

A PREFACE

During my training in Bratislava with Professor Červenansky and in practice as head of the Orthopaedic Department in Liberec, Low Back Pain always was a main interest

Professor Carl Hirsch was at that time by reputation a well known name to me and I was all the happier to be able to work with him when I came to Sweden in 1965. Since then he has been my appreciated chief at the Orthopaedic Department at Sahlgrenska Sjukhuset in Gothenburg. From the depth of my heart I thank him for helping me to get started in Sweden and for his encouragement and advice during all phases of this investigation.

At the request of Arbetsmarknadens Försäkringsaktiebolag (the Industrial Labour Market Insurance Company) and after consultation with Professors C. Hirsch, B. Lindegård and H. Hyrenius about the necessity of gathering further information about the somatic pattern of disease and the social problems involved in pain of the spine, Professor Hirsch requested me to study the somatic problem. Doctor Claes Goran Westrin was entrusted with the analysis of the socio-medical problems. I am extremely grateful to Professors C. Hirsch, B. Lindegård and H. Hyrenius who have enabled me to fulfil my study and publish the results. I also wish to include Doctor Claes Goran Westrin in these acknowledgements.

I am deeply indebted to Esbjörn Carlström, Ph.D., Department of Statistics, University of Gothenburg, for his invaluable help in planning the statistical analysis. My thanks go to Ass. Professor Sven Scheller and Doctor Olof Blom for organizing the radiographic examination and interpretation of the radiographs to Miss Ingegerd Jansson (Göteborgs Datacentral för Forskning och Högre Utbildning) responsible for the data processing work, Mrs. Inga Lisa Elzer for making the diagrams and Mrs. Birgitta Pande for secretarial help.

I wish to thank Ass. Professor Svante Rolander for all his valuable help in constructive criticism and much appreciated advice.

The investigation was made possible by generous grants from Arbetsmarknadens Försäkringsaktiebolag and the Medical Association of Gothenburg.

Gothenburg in February 1969

JIRI HORAL

At the present time many authors attribute great importance to the intervertebral disc ¹⁾

On the other hand it is known that degeneration of a disc frequently occurs also among subjects who had never experienced low back pain (Bistrom 1954 Hirsch 1955). Consequently if lumbar symptoms are caused by changes in a disc the pain mechanism ²⁾ remains to be investigated. ³⁾

There are various types of low back disorders ²⁾

Even if anatomical pathological and physiological investigations point to the disc being the source of back pain, it is believed that patho-physiological complex combinations are involved (Barr 1951 Hirsch 1965) ⁴⁾

This investigation was begun in order to study clinically and roentgenologically two statistically comparable populations. They were differentiated at the selection merely by the fact that one group included those reported sick by a physician due to low back disorders the other group had not been sick listed. The purpose of this investigation was mainly to determine the frequency and the development of different types of low back disorders and to compare the various subjective symptoms with the objective findings

D SURVEY OF LITERATURE

The compiled series of patients with low back disorders revealed the various types of spinal disorders and their medical importance in general as well as socially. Comparisons were made between past histories, clinical and roentgenological findings. Certain anatomical elements of the lumbar spine had been subject to morphological, physiological, biochemical and biomechanical analyses and assessments. Numerous clinical series consist of selected patients who due to spinal disease consulted at orthopaedic clinics (*Helleg 1920, Jansen 1926, Yeoman 1928, Siensstrom 1931, Friberg 1939, Bradford et Spurling 1939, Friberg 1941, Meyerding 1941, Bradford et Spurling 1947, Falconer, McGeorg et Begg 1948, Friberg et Hirsch (1949), Soderberg 1956, Retting 1959, Sparup 1960*).

Other authors carried out investigations on various groups of the population (*Unander Scharin 1950, Hult 1954 a b, Hult et Forsman 1957, Schioetz 1957, Kellgren et Laurence 1958, Faxen 1959, Lundberg 1959, Lokander 1962, Blomquist, Bergmark et Lindgren 1964, Zeiner, Henriksen 1966, Lundberg, Broman, Hansson, Vilhelmsson 1966, Faxen 1968, Hirsch, Jonsson et Lewin 1968*). Varying selections of patients and controls often prevented comparisons between different series.

Unander Scharin (1950) collected data about patients sick listed for lumbar spine disorders at the Stockholm City Central Sick Benefit Society and at the Stockholm Tramway Company. Out of the total sick listed during 1948 and belonging to one of the above mentioned groups 4.5 per cent had low back pain or sciatica.

Hult (1954 a b) performed an investigation to detect existing cases of spinal disorders of two populations. His Munkfors Investigation comprised 100 boys aged 8—11 years, 100 apprentices aged 15—20 years, 114 woodsmen and 163 industrial workers aged 35—39 years. His monography "Cervical Dorsal and Lumbar Spinal Syndrome" was based upon 1193 labourers aged between 27—59 years with light and heavy work. Wry neck, brachialgia and lumbar syndrome were frequently found among the examined subjects. Cervicalgia and/or brachialgia had a frequency of 50.6 per cent in subjects with light work and of 51.1 per cent in those with heavy labour. Lumbar syndrome occurred in 52.7 per cent among the light workers and among those with heavy labour the figure was 64.4 per cent. In the "Munkfors-Investigation" low back disturbances amounted to 79.9 per cent while thoracic spine disorders only reached about 5 per cent. The author pointed out a correlation between roentgenological findings and cervical and lumbar spine disturbances but no correlation between spinal disorders and various physical build or moderate deformities in the spine or the lower extremities.

C INVESTIGATIONAL PROBLEMS

This investigation deals with the following questions

Which are the differences between patients sick listed earlier for low back disorders (*probands*) and previously non sick listed subjects (*controls*) regarding

- 1 Different types of low back disorders
- 2 Symptoms of various low back disturbances and their correlation
- 3 Recurrence
- 4 Subjective experience of low back disorders
- 5 Objective findings on examination
- 6 Presence of cervical — and thoracic spine disorders
- 7 Roentgenological findings
- 8 Prognosis of various types of low back disorders

days during this period 15.19 per cent males 9.96 per cent gainfully employed females and 4.33 per cent housewives were subjected to thoracic and lumbar spine disorders

Hirsch Jonsson et Larm (1968) interviewed 692 females in three of the Gothenburg districts which statistically represented the female population of the country. Among those there was lumbar spinal disorders in 49 per cent. The development of different types of lumbar spine disorders, age at onset and number of recurrences was stated. The reliability of the past history was checked at renewed interviews.

Many of the clinical studies also include radiographic changes found in the series to be investigated. The authors were mainly interested in existing degeneration of the disc, deformities, spondylosis and congenital spinal changes.

Badgley (1937) found that a reduction of the lower lumbar intervertebral spaces occurred more often in patients with sciatica than with lumbago.

Hodges et Peck (1937) who compared Badgley's cases with a larger number of controls found significantly more often a reduced intervertebral space in patients with lumbago and sciatica than in the controls (45.1). The same phenomenon applied to congenital anomalies (2.1). Contrary to this spondylarthrosis was found rather often in the controls as compared to the patients. The importance of the investigation becomes reduced however as the controls were not statistically matched with the patients suffering from lumbago and sciatica. Their mean age was slightly lower and they had come to the clinic because of spinal disorders but of a different type to lumbago and sciatica.

Sjöström (1943) examined 210 patients with degeneration of the lumbar discs which had been verified roentgenologically. No other changes were observed on the radiographs. The greatest frequency of degeneration of the disc was found by the author to occur between 31 and 55 years. The severity of the disc degeneration in his material did not show any parallelism with age. Bistrom (1954) examined 151 individuals with a healthy spine and found that spondylosis clearly depended on the age and occurred earlier in males than in females. Spondylosis and spondylolysis were found in 14.3 per cent, transitional vertebrae in 20 per cent, asymmetrical transitional vertebrae in 4.6 per cent.

Hult (1954 a, b) stated that degeneration of a disc depends on the age and can be regarded as a physiologic process.

Much attention was given roentgenologically verified and clinically important congenital changes of the spine. Hibbs et Swift (1929) stated that congenital changes cause instability which result in spinal disorders. Willis (1932) wrote that congenital changes and asymmetrical sacralization and lumbarization are of clinical interest due to reduced resistance to damage or disease. Later (1941) he found a greater incidence of anomalies in cases with aching lumbar spine than in those without symptoms. Ingelrigsen (1937) believed that asymmetrical sacralization is of great pathogenetic importance in spinal disorders. In his series of patients

Low back pain was more often found in manual workers but the author mentions that the work in itself cannot be the cause of the spinal disease

Schiøtz (1957) found in the Oslo Trygdekasse that of the total number of sick days, low back pain and sciatica amounted to 7.3 per cent

Kellgren et Laurence (1958) clinically and radiographically, examined a series selected at random in a British town (Leigh), 170 males and 145 females aged between 55—64 years. In males of this comparatively high age there were cervical and lumbar degeneration of the discs in 69—83 per cent and the females revealed a percentage of between 52—72 per cent

Faxen (1959) in checking the local branch of the National Health Insurance Service in suburban areas of Gothenburg during 1955—1957 found that spinal disease in males amounted to 11.74 per cent of all the sick cases and 15 per cent of all days lost through illness, and was merely surpassed by upper respiratory infections. In females the corresponding figures were 5.53 per cent of all sick cases and 8.36 per cent of all days lost through illness, and thus held the third place after psychic insufficiency and upper respiratory infections

Lindberg (1959) stated that 9 per cent of all the days lost through sickness depended on spinal disorders. The author calculated on the compensation merely for spinal disorders to the population of Gothenburg (397 205 subjects) amounting to more than 4 mill Sw Kr in 1958

Iokander (1962) stated that at ASEA in Vasteras the spinal disorders amounted to 20 per cent of the total number of days lost through sickness

Zeiner Henriksen (1966) studied the rate of sick listed members and the morbidity among male patients with sciatica belonging to the Oslo Health Insurance. He excluded those who were hospitalized on the diagnosis sciatica. For comparison a control group was used which however was not matched with the patients. He proved that patients with sciatica more often had nervous or psychic disturbances and alcohol problems than their control group. Furthermore patients subjected to surgery had a less number of morbid conditions than those conservatively treated. *Lindberg Broman Hansson Vilhelmsson* (1964) found that the city of Gothenburg with a population of 418 600 had 17 000 persons aged between 16—64 years who suffered from spinal disease. This figure exceeds the number of patients with heart insufficiency by four and is twice the number of other diseases in the extremities as known to the National Health Insurance Office. By including other localization of spinal disease the figure increases to 22 000 patients who were aged between 16 and 24 years during 1964 in Gothenburg the females constituting 50.8 per cent. Only 13.6 per cent of these patients were capable of work despite continued symptoms. 36.8 per cent were sick listed for more than 90 days. The authors maintained that 50 per cent of the patients with spinal disease ought to have medical attendance

Faxen (1968) compiled the figures from the decade 1955—1965 at the Mölndal National Health Insurance Office (population 37 240 in 1965). Of all the sick

days during this period 15.19 per cent males 9.98 per cent gainfully employed females and 4.35 per cent housewives were subjected to thoracic and lumbar spine disorders

Hirsch Jonsson et Lewin (1968) interviewed 692 females in three of the Gothenburg districts which statistically represented the female population of the country. Among those there was lumbar spine disorders in 49 per cent. The development of different types of lumbar spine disorders, age at onset and number of recurrences was stated. The reliability of the past history was checked at renewed interviews.

Many of the clinical studies also include radiographic changes found in the series to be investigated. The authors were mainly interested in existing degeneration of the disc, deforming spondylosis and congenital spinal changes.

Badgley (1937) found that a reduction of the lower lumbar intervertebral space occurred more often in patients with sciatica than with lumbago.

Hodges et Peck (1937) who compared Badgley's cases with a larger number of controls found significantly more often a reduced intervertebral space in patients with lumbago and sciatica than in the controls (4.5:1). The same phenomenon applied to congenital anomalies (2:1). Contrary to this spondylarthritis was found rather often in the controls as compared to the patients. The importance of the investigation becomes reduced however as the controls were not statistically matched with the patients suffering from lumbago and sciatica. Their mean age was slightly lower and they had come to the clinic because of spinal disorders but of a different type to lumbago and sciatica.

Seerin (1943) examined 210 patients with degeneration of the lumbar discs which had been verified roentgenologically. No other changes were observed on the radiographs. The greatest frequency of degeneration of the disc was found by the author to occur between 31 and 55 years. The severity of the disc degeneration in his material did not show any parallelism with age. Bostrom (1954) examined 151 individuals with a healthy spine and found that spondylosis clearly depended on the age and occurred earlier in males than in females. Spondylosis thesis and spondylosis lysis were found in 14.3 per cent transitional vertebrae in 20 per cent asymmetrical transitional vertebrae in 6.6 per cent.

Hult (1954 a, b) stated that degeneration of a disc depends on the age and can be regarded as a physiologic process.

Much attention was given roentgenologically verified and clinically important congenital changes of the spine. Hibbs et Swift (1929) stated that congenital changes cause instability which results in spinal disorders. Willis (1932) wrote that congenital changes and asymmetrical sacralization and lumbarization are of clinical interest due to reduced resistance to damage or disease. Later (1941) he found a greater incidence of anomalies in cases with aching lumbar spine than in those without symptoms. Ingebrigtsen (1937) believed that asymmetrical sacralization is of great pathogenetic importance in spinal disorders. In his series of patients

Low back pain was more often found in manual workers but the author mentions that the work in itself cannot be the cause of the spinal disease

Schiotz (1957) found in the Oslo Trygdekasse that of the total number of sick days, low back pain and sciatica amounted to 7.3 per cent

Kellgren et Lawrence (1958) clinically and radiographically examined a series selected at random in a British town (Leigh), 170 males and 145 females aged between 55–64 years. In males of this comparatively high age there were cervical and lumbar degeneration of the discs in 69–83 per cent and the females revealed a percentage of between 52–72 per cent

Faxen (1959) in checking the local branch of the National Health Insurance Service in suburban areas of Gothenburg during 1955–1957 found that spinal disease in males amounted to 11.74 per cent of all the sick cases and 15 per cent of all days lost through illness and was merely surpassed by upper respiratory infections. In females the corresponding figures were 5.53 per cent of all sick cases and 8.36 per cent of all days lost through illness and thus held the third place after psychic insufficiency and upper respiratory infections

Lundberg (1959) stated that 9 per cent of all the days lost through sickness depended on spinal disorders. The author calculated on the compensation merely for spinal disorders to the population of Gothenburg (397 205 subjects) amounting to more than 4 mill Sw Kr in 1958

Lokander (1962) stated that at ASEA in Vasteras the spinal disorders amounted to 20 per cent of the total number of days lost through sickness

Zeiner Henriksen (1966) studied the rate of sick listed members and the morbidity among male patients with sciatica belonging to the Oslo Health Insurance. He excluded those who were hospitalized on the diagnosis sciatica. For comparison a control group was used which however was not matched with the patients. He proved that patients with sciatica more often had nervous or psychic disturbances and alcohol problems than their control group. Furthermore patients subjected to surgery had a less number of morbid conditions than those conservatively treated. *Lindberg Broman Hansson Vilhelmsson* (1964) found that the city of Gothenburg with a population of 418 600 had 17 000 persons aged between 16–64 years who suffered from spinal disease. Incidence of thoracic spine syndromes with/without radiating pain.

with lumbar spine disorders *Brofeldt* (1937) reported a high frequency of asymmetrical sacralization with scoliosis (18.1 %) and spondylolisthesis and spondylolysis (21.5 %). *Friberg* (1939) found sacralization in 5.3 per cent hemivertebra in 1.6 per cent, spondylolisthesis and spondylolysis in 6.3 per cent and other congenital changes in 2.4 per cent. *Murali* (1949) in his series of 124 patients who were operated for prolapsus of a disc reported sacralization in 15.3 per cent. *Rettig* (1959) believed that slight disturbance in the development of the lumbar and sacral spine rarely causes inconvenience, but that by no means must it be disregarded due to reduced resistance and a predisposition for spinal disorders as a result. *Makovicky* (1963) found congenital changes of the vertebrae in 45 per cent of the examined subjects selected at random.

There are great variations in the literature as regards the etiology. The various principles of selection when collecting clinical data are also responsible for the calculation of spinal symptoms.

1 Selection of Series and Statistical Analysis

This investigation deals with a series which was selected with the intention of elucidating it from both the socio-medical and orthopaedic points of view. Consequently a group selected at random and sick listed due to low back disorders — *probands* — was compared with a matched group of individuals — *controls* — who had not been sick listed during the period from 1st January 1955 until 1st January 1967. The investigation began in 1966. The probands were selected among those who had been sick listed for low back disorders during 1964.

In reviewing the records of the National Health Insurance Service at Gothenburg which in 1964 called 450 000 inhabitants it was found that approximately 17 000 persons had been incapable of work for long or short periods due to spinal disorders. The number of patients reported sick by their physicians was considerably less however and amounted to about 9 000 persons. From the latter group random selections were made of those born on the first day of each month.

Notice. In Sweden each member of the National Health Insurance can report his or her illness over the telephone without having to produce a doctor's certificate. This type of "self-sick listing" is valid no longer than one week. Starting from January 1st 1967 compensation is paid as from the first day of sick listing. Previously a waiting period of three days elapsed and from the fourth day compensation was paid out. Should the patient consider it necessary for him to extend his period of sick listing a doctor's certificate must be produced at the end of the first week.

The group of probands consists of patients sick listed by physicians in 1964 for lumbar spine disorders during at least one week. Only those with a diagnosis of primary spinal disorders were regarded as probands while those with any other disease were excluded even if lumbar spine disorders were present as a second diagnosis. For practical and statistical reasons it was decided that only Swedish born members would be included. The number of primary selected probands was 277. Five of the probands died after 1964 and three moved elsewhere. Some refused to partake in the examination and thus the proband series comprised 43 individuals which was 87.7 per cent of the original number and 90.3 per cent of those summoned. Each selected proband was "matched" with a control.

The controls had not been reported sick by a doctor for lumbar spine disorders from 1955 at which time the National Health Service began until 1st January 1967 when the actual investigation was commenced.

1 Selection of Series and Statistical Analysis

This investigation deals with a series which was selected with the intention of elucidating it from both the socio-medical and orthopaedic points of view. Consequently, a group elected at random and sick listed due to low back disorders — *probands* — was compared with a matched group of individuals — *controls* — who had not been sick listed during the period from 1st January 1955 until 1st January 1967. The investigation began in 1966. The probands were selected among those who had been sick listed for low back disorders during 1964.

In reviewing the records of the National Health Insurance Service at Gothenburg which in 1964 totalled 450 000 inhabitants it was found that approximately 17 000 persons had been incapable of work for long or short periods due to spinal disorders. The number of patients reported sick by their physicians was considerably less however and amounted to about 9 000 persons. From the latter group random selections were made of those born on the first day of each month.

Notice. In Sweden each member of the National Health Insurance can report his or her illness over the telephone without having to produce a doctor's certificate. This type of self sick listing is valid no longer than one week. Starting from January 1st 1967 compensation is paid as from the first day of sick listing. Previously a waiting period of three days elapsed and from the fourth day compensation was paid out. Should the patient consider it necessary for him to extend his period of sick listing a doctor's certificate must be produced at the end of the first week.

The group of probands consists of patients sick listed by physicians in 1964 for lumbar spine disorders during at least one week. Only those with a diagnosis of primary spinal disorders were regarded as proband while those with any other disease were excluded even if lumbar spine disorders were present as a second diagnosis. For practical and statistical reasons it was decided that only Swedish born members would be included. The number of primary selected probands was 777. Five of the probands died after 1964 and three moved elsewhere. Some refused to partake in the examination and thus the proband series comprised 743 individuals which was 87.7 per cent of the original number and 90.3 per cent of those summoned. Each selected proband was matched with a control who corresponded with regard to sex, age and sickness benefit category (= income). The controls had not been reported sick by a doctor for lumbar spine disorders from 1955 at which time the National Health Service began until 1st January 1967 when the actual investigation was commenced.

Out of 269 controls 235 were willing to partake in this investigation (87.4%). Due to non response in both groups, 424 individuals were available, viz 212 matched pairs for comparison which constituted 76.6 per cent of all the primarily selected probands and 78.8 per cent of all the primarily selected controls. The others were excluded from the investigation. Each group of probands and controls included 125 males (59%) and 87 females (41%).

The series classified in groups of probands and controls gave a selection which permitted statistical analyses and comparisons, and enabled the problems of this investigation to be dealt with. Controls with previous lumbar spine disorders and those without previous symptoms could be compared with each other and with the probands with which they were matched.

After the author personally had examined each of the 424 subjects, all the results were transferred to a code system and then to a punch card (272 columns for each subject) for data processing. The data obtained were tabulated and various groups and classifications were statistically analysed, where the probabilities were expressed in chi square (X^2) or the t test together with Degree of Freedom (df). Only significant X^2 — or t test values were included. When calculating the mean values and the mean ages, the Standard Error (SE) was given. In most of the tables both absolute figures and percentage are indicated.

2 Clinical Examination

In order to avoid subjective bias the author at the time of examination in 1967 was unaware of the fact whether the subject was a control or a proband. When the entire series had been examined this piece of information was added to the code system. For the same reason the examination was first made without previous knowledge of the past history. Afterwards the past history was enquired into and included in the code system together with the findings. At the examination several techniques were used as described by the American Academy of Orthopedic Surgery (1965) *Simmons* (1966) and by *Hirsch* and *Hult* in Chapters 15 and 16 respectively of *Nordisk Larobok i Ortopedi* (Scandinavian Textbook of Orthopaedic Surgery 1959).

The examination began with inspection of the general condition, body structure, gait, obvious deformities and detailed examination of extremities and spine followed by palpation of the latter parts. Special attention was paid to tenderness in spinal processes and to the paravertebral musculature both in standing and reclining positions. Any deviation of the pelvis was measured. The function of the extremities and the spine was examined, differences in symmetry measured and distance between finger tips and floor at maximal flexion of back and hip joints was noted. Conclusively the upper and lower extremities were subjected to neurological examination. Merely results of statistical value or of some clinical importance were included.

3 Case History

Previously arranged questions were asked by the author and noted. The subjects were first asked about existing low back pain. As *Houorth* (1962) mentions by beginning with questions which are of interest to the patients it will be easier to bring out a more reliable past history. When the subject admitted to symptoms they were asked about their opinion of the cause, character, localization, intensity and whether they experienced restriction of movement in connection with low back pain. Enquiries were then made about details as to the onset, number of recurrences and possible symptoms in 1964. At the examination a question was asked whether or not the subject had had any lumbar spine disorder during the past three or four years. Questions regarding the precise time of illness could cause a lapse of memory by the subject and were consequently not predominant. Both probands and controls were questioned as to previous symptoms from the cervical and thoracic spine. When the examination was completed a diagnostic summary was made both retrospectively and on the basis of the past history only and clinically on the basis of the objective findings and symptoms on examination in 1967.

4 Reliability of Past History and Sources of Error

The past history is based upon the subjects own history which should be taken *cum grano salis* (*Magnusson* 1968). Lapse of memory and imaginary symptoms can never be quite excluded. *Blomquist, Bergmark et Lindgren* (1962) showed on examination of patients sick listed during at least 90 days in Stockholm, Gothenburg, Malmö and Norrköping that the diagnosis in the doctor's report to the National Health Service, as a rule, always can be accepted.

In a later investigation of joint subjects *Westrin* (to be published) will analyse the reliability of past histories as stated to the author and himself on different occasions and the sources of error. Thus he will prove that the past history in some cases is reliable, in others it deviates.

F INTRODUCTION OF SERIES

Fig 1 Number and Percentage of Subjects in the Various Age Groups

1 Age Distribution

The series included 424 examined subjects. There were 125 males and 87 females together 212 probands and an equal number of matched controls. The mean age of both probands and controls at the time of examination in 1967 was for males 49.48 ± 1.07 years and for females 47.71 ± 1.34 years. There was no significant statistical deviation.

In this series the morbidity of males and females increases up to the age of between 50 and 59 years even if the increase in morbidity of females as compared to the age group 40—49 years only was 6.1 per cent (1 individual). Then the morbidity rapidly declines. There was a slight decrease in the number of females in the ages between 30 and 39 years of age probably due to the small number of examined subjects in this age group. One female proband and one female control had reached the age of 71 years at the time of examination. The proband, however, was sick listed in 1964 because of low back pain.

2 Definition of Slight and Intense Pain/Ache

It is impossible to determine the degree of ache without prejudice, as it is a subjective sensation. The subjects were asked to give as detailed a definition as possible about their sensation of pain. The more or less synonymous expressions which were used are

TABLE 1 Subjective Sensation of Pain on Various Occasions

	Onset				Majority of Recurrences			
	P		C		P		C	%
Intense pain	156	73.9	79	56.0	79	41.6	25	26.6
No intense pain	55	26.1	62	44.0	111	58.4	69	73.4
Total	211	100.0	141	100.0	190	100.0	94	100.0

($\chi^2 = 12.21^{***}$ d.f. = 1)

($\chi^2 = 6.00^*$ d.f. = 1)

1964 (1963—1966)

On Examination 1962

	P		C		P		C	%
Intense pain	147	69.7	30	33.0	13	12.0	1	1.8
No intense pain	64	30.3	61	67.0	95	88.0	55	98.2
Total	211	100.0	91	100.0	108	100.0	56	100.0

($\chi^2 = 35.30^{***}$ d.f. = 1)

($\chi^2 = 4.96^*$ d.f. = 1)

F INTRODUCTION OF SERIES

Fig 1 Number and Percentage of Subjects in the Various Age Groups

On some occasion intense pain/ache in the lumbar spine had been experienced by 177 probands (83.9%) and 90 controls (63.8%) 156 probands (73.9% of the entire series) and 79 controls (56% of all subjects with previous spinal disorders) had experienced intense pain at the onset. However only 37.4 per cent of the probands and 12.7 per cent of the controls with lumbar spine disorders had had the same sensation at most of the recurrences.

The results show that 50.6 per cent of the probands who claimed intense pain at the onset had the same sensation also at most of the recurrences. On the other hand only 22.8 per cent of the controls had the same sensation at onset and recurrence. The difference is statistically significant ($\chi^2=7.23^{**}$ d.f. = 1).

If the above results are compared with Table 1 it is found that all the probands who had intense pain at most of the recurrences also experienced this at the onset of low back disorders. Out of 25 controls with intense pain at most of the recurrences 72 per cent mentioned that they had intense pain at the time of onset.

Correlation between intensity of pain and consultation with physician

All the probands consulted a physician due to low back pain, but only 72 (51.1%) of the controls. The difference is statistically significant ($\chi^2=125.11^{***}$ d.f. = 1). Out of the 90 controls who at some time had experienced intense pain/ache in the lumbar spine 69 consulted a physician. Out of 51 who only had slight pain/ache in the lumbar spine three consulted a physician ($\chi^2=44.83^{***}$ d.f. = 1 $\chi^2=73.51^{***}$ d.f. = 1) applies to both cases and to the probands and the controls respectively and is statistically highly significant.

The controls who had experienced intense pain in the lumbar spine were asked why they had not consulted a physician. Most of them answered that they had not considered their illness as serious and were very busy with their work or that they had tried pain relieving pills first and possibly a few days of sick leave. The same answer was given by a female control who had objective signs of sciatica at the time of examination in 1967.

Consulted physician according to distribution of lumbar spine diagnoses at the examination 1967 — see separate Table 2.

Summary In studying the development and duration of pain the probands as compared to the controls have a statistically significant higher frequency of low back pain which they experienced as intense both at the time of onset and at the recurrences. The controls even in connection with intense pain often had not consulted a physician and almost never when the pain was slight.

Sensation of low back pain

The development and duration of low back pain at the onset in 1964 and at the time of investigation in 1967 was studied in detail.

1 Solid pain 2 Intense pain 3 Flashing pain 4 Sharp pain 5 Spasmodic pain
 6 Terrific pain 7 Feels like a boil 8 Intense dull pain 9 Feeling of discomfort
 10 Feeling of exhaustion 11 Feeling of stiffness 12 Slight pressing pain
 13 Mild dull pain 14 Insignificant pain Using a somewhat arbitrary estimation,
 Nos 1-8 were included into one group under the designation intense pain/
 ache and the remaining were called slight pain/ache

A statistically significant larger group of probands as compared to the controls
 claimed intense pain/ache at each examination. The significance of low back pain
 was greatest in 1964, and lowest at the examination

The probands and controls who at the onset of low back pain claimed intense
 and slight pain/ache respectively were compared with respect to their age

TABLE 2 Degree of Pain at First Onset

	Intense pain/ache at first onset				Slight pain/ache at first onset			
	P	%	C		P	%	C	%

Mean age \pm SE

P = 35.51 \pm 1.15 years

C = 33.61 \pm 1.38

Mean age \pm SE

P = 34.36 \pm 1.92 years

C = 35.81 \pm 1.99

There were no significant differences in the mean age and the age distribution
 in comparison with the probands and the controls. Similar results were found
 also in the age distribution of those who claimed intense and slight pain/ache
 respectively in connection with most of the recurrences and around 1964

A statistically significant higher frequency of intense pain sensation in subjects
 earlier sick listed for low back pain justified an investigation. The aim was to
 find out the prognostic value of pain sensation and also to determine whether the
 subject in connection with recurrences experienced pain of the same intensity

Most of the cases of sciatica (45 %) were found among the probands in 1964. The greatest number of controls with sciatica (21.9 %) occurred at the time of onset. In both groups the lowest frequency of sciatica diagnosed at the time of examination in 1967 was 22.2 per cent among the probands and 10.7 per cent among the controls.

Sciatica occurred in a statistically significant higher degree among the probands sick listed in 1964 than among the controls who were not sick listed ($\chi^2=17.3^{***}$ $df=1$). The χ^2 test of the recurrences is not statistically significant.

Summary Low back pain and sciatica was found in probands and controls on different occasions. Even if the memory had slipped some of the subjects the collected data seem to be logical, however. The greatest number of cases of sciatica was found in the probands in 1964 i.e. the time at which all were sick listed. The controls experienced the most intense pain at the onset of the disease, mostly before 1955, when their illnesses were not yet recorded at the National Health Service. When discussing the development and duration of pain it was pointed out that most of the probands and the controls had experienced the onset of low back disorders as the most severe attack. A combined sensation of intense pain and radiating pain/ache, therefore, is not surprising.

3 Definition of Various Low Back Disorders (Low Back Insufficiency, Lumbago, Sciatica)

Based upon the past history and on the first symptoms the subjects were classified in four groups: previously healthy, low back insufficiency, lumbago and sciatica.

The variations in the disease during numerous recurrences were followed up from the onset and in 1964 at which time the probands were sick listed up to the first six months of 1967 when the examination took place.

Low back insufficiency included sensation of tiredness, weakness, stiffness and dull pain in the back. The signs may vary in intensity and duration and may be connected with any stress to which the spine is subjected.

Lumbago is characterized by an acute, localized pain or ache which appears at the onset in the lumbar spine with restricted movement as a result.

Sciatica can be recognized by radiating pain/ache of a radicular kind in the legs. The intensity of the pain varies and other symptoms such as a feeling of weakness of the legs, paraesthesia and a sensation of numbness occur. All the groups were classified in so-called "consistency cases" and "variations". As "consistency cases" were regarded subjects who from the time of onset until the time of examination only had one and the same type of low back disorder. In cases where the pattern varied, e.g. from sciatica to lumbar spine insufficiency or from lumbago to sciatica, the term "variations" of sciatica with lumbar spine insufficiency and variation of lumbago with sciatica was employed.

TABLE 3 Sensation of Low Back Pain

	Low Back Pain at Onset		Around 1964		On Examination in 1967	
	P	C	P	C	P	C
Pain day and night	115	48	100	15	13	1
Only with movement	61	53	67	32	18	9
Only with strain	22	29	28	32	42	23
Other reasons	13	11	16	12	35	23
Total	211	141	211	91	108	56

A statistically significant higher number of probands than controls stated that they had pain day and night at the time of onset and even during the sick listing period in 1964 ($X^2=15.9^{**}$ $df=3$) at the time of onset and ($X^2=33.7^{***}$ $df=3$) during 1964

About half of all the probands mentioned that the pain carried on day and night on both occasions. Corresponding data, given by the controls were at the time of onset 34 per cent and 16.5 per cent in 1964.

About 40 per cent of both probands and controls at the time of examination experienced pain only in connection with strain, 18.5 per cent of the probands and 26.8 per cent of the controls had pain when standing or sitting for a long time.

For further details of the above mentioned chapter and for comparison between subjects with intense — slight pain/ache respectively see separate Table 3.

Summary A statistically significant higher frequency of probands as compared to the controls had continuous low back pain both at the time of onset and around 1964. Low back pain in connection with certain movements or strain occurred more often among the controls than the probands.

Localization of pain

The past history revealed how often the symptoms were localized only to the lumbar spine and how often sciatica occurred. Only characteristic radicular radiating pain was accepted as sciatica.

TABLE 4 Localization of Pain

	Onset		Around 1964		On Examination in 1967	
	P	%	P	%	P	%
Lumbar Sacral Spine	150	71.6	109	78.1	116	55.0

Total	211	141	211	91	108	56

A statistically significant higher number of probands than controls stated that they had pain day and night at the time of onset and even during the sick listing period in 1964 ($X^2=15.9^{**}$ $df=3$) at the time of onset and ($X^2=33.7^{***}$ $df=3$) during 1964

About half of all the probands mentioned that the pain carried on day and night on both occasions. Corresponding data given by the controls were at the time of onset 34 per cent and 16.5 per cent in 1964.

About 40 per cent of both probands and controls at the time of examination experienced pain only in connection with strain. 18.5 per cent of the probands and 26.8 per cent of the controls had pain when standing or sitting for a long time.

For further details of the above mentioned chapter and for comparison between subjects with intense — slight pain/ache respectively, see separate Table 3.

Summary A statistically significant higher frequency of probands as compared to the controls had continuous low back pain both at the time of onset and around 1964. Low back pain in connection with certain movements or strain occurred more often among the controls than the probands.

Localization of pain

The past history revealed how often the symptoms were localized only to the lumbar spine and how often sciatica occurred. Only characteristic radicular radiating pain was accepted as sciatica.

TABLE 4 Localization of Pain

	Onset				Around 1964				On Examination in 1967			
	P	%	C	%	P	%	C	%	P	%	C	%
Lumbar Sacral Spine	150	71.6	109	78.1	116	55.0	73	80.2	84	77.8	50	89.3
Sciatica	60	28.4	31	21.9	95	45.0	18	19.8	24	22.2	6	10.7
Total	211	100.0	141	100.0	211	100.0	91	100.0	108	100.0	56	100.0

According to their own statements only 8 probands and none of the controls were incapacitated for work due to low back disorders at the time of examination. A statistically significant greater frequency of probands with previous low back pain and further at the examination in 1967 was noted as compared to the controls. In the control group 66.5 per cent (66.7 % females and 66.4 % males) complained of previous low back pain and 33.5 per cent (33.3 % females and 33.6 % males) had never had any symptoms or signs. Out of the 71 subjects who had never had any low back disorders 40.8 per cent were females and 59.2 per cent males. The distribution of sex in this group was almost identical with those who had low back disorders. The distribution of age in those who had never had symptoms did not differ either when compared with the other subjects. The greatest number of previously symptom free males were aged between 50 and 59 years and the females were between 40 and 49 years of age.

The mean age in males was 48.81 ± 7.14 years and in females 47.24 ± 7.59 years. There is no difference in the figures as compared with those of low back pain symptoms.

TABLE 6 Distribution of Age in Controls According to Past History

Age	Low Back Pain Symptoms		No Symptoms	
	Males	Females	Males	Females
20-29	4	7	7	5
30-39	9	6	6	2
40-49	26	19	5	7
50-59	31	15	12	12
60-69	13	11	12	2
70-	0	0	0	1
Total	83	58	42	29

Of the subjects who had never earlier had low back pain 31 had experienced disorders in the cervical and thoracic spine. The mean age of the remaining 40 controls who had been symptom free in the entire spine was 47.62 ± 7.23 years and included the oldest control i.e. there was no difference in comparison with other groups. For further details of the above mentioned chapter see separate Table 4.

Summary The incidence of low back disorders in the present control series is high and includes 66.5 per cent of the controls. This selection is not characteristic of an epidemiological picture of the population; the reason being that the examination was based upon a principle of selection where all cases of lumbar spine disorders which may exist were not included. No difference in sex

When the author guided by the case history of the probands and the controls in different groups of lumbar spine syndrome, attempted to use the terms "lumbago chronicum" and "lumbar spine insufficiency" it was found that lumbago chronicum and spinal insufficiency only in extreme cases could be clearly differentiated. In most cases it was very difficult to distinguish between the two groups due to a great overlap when obtaining the symptoms. Therefore, the author has included lumbago chronicum in his classification "lumbar spine insufficiency".

"Coaching ache" is due to fatigue of the musculature owing to unusual labour. When localized in the lumbar spine it has not been regarded as a spinal disease.

4 Incidence of Low Back Disorders in Probands and Controls

Back disorders is a general term including all kinds of pain and discomfort in the spine.

TABLL 5 Existing Low Back Pain Based Upon Interviews in 1967

	P	%	C	%
Low Back Pain prior to examination in 1967	211	99.5	141	66.5
No Low Back Pain prior to examination in 1967	1	0.5	71	33.5
Total	212	100.0	212	100.0
$(X^2=81.98^{***} \text{ df}=1)$				
Subjects with symptoms also on exam in 1967	108	51.2	56	39.7
Subjects with previous symptoms but without symptoms on exam in 1967	103	48.8	85	60.3
Total	211	100.0	141	100.0
$(X^2=4.47^* \text{ df}=1)$				

211 probands and 141 controls had low back pain prior to but not at the actual examination in 1967. One proband also at the second interview did not admit to spinal disorders, no doubt depending on lapse of memory. Of those with previous disorders, 51.2 per cent of the probands and 39.7 per cent of the controls had low back pain at the examination in 1967.

of the controls. There was no statistically significant difference when comparing the subjects who had symptoms. The distribution of sex revealed a small significant difference ($X^2=4.35$ d.f. = 1) between female and male controls.

Distribution of age

The differences in distribution of age between probands and controls in low back disorders are given in Table 7.

TABLE 7 Age Dependence of Low Back Disorders

		20-29	30-39	40-49	50-59	60-71	20-71
Insufficiency	P	9 24.2	4 10.5	8 21.0	10 26.3	7 18.0	38 100.0
	C	5 11.1	9 20.0	16 35.6	7 15.6	8 17.7	45 100.0
Lumbago	P	11 9.7	11 9.1	30 26.5	39 25.7	22 28.4	113 100.0
	C	4 6.2	6 9.2	17 26.2	30 46.1	8 12.3	65 100.0
Sciatica	P	3 5.0	8 13.3	18 30.0	21 35.0	10 16.7	60 100.0
	C	2 6.5	0 —	12 39.0	9 29.0	8 25.5	31 100.0

Low back insufficiency was found to have a high frequency already among the young probands and remained stable after the age of 29 years with the exception of a slight increase in females ranging from 50 to 59 years. In the control subjects the increase continued up to the age group of 40-49 years after which it rapidly declined.

The frequency of lumbago is comparatively low in the ages from 20-29 years with only 9.7 per cent of probands and 6.2 per cent of controls who had symptoms. There was no increase in the probands belonging to the next decade and only a slight increase in the controls. The highest frequency of lumbago was found in the probands ranging from 40-49 years and 50-59 years in the controls (26.5 per cent and 46.1 per cent, respectively). After the age of 60 years the probands maintained the same figures but the controls revealed a decrease of only 12.3 per cent.

In the ages 20-29 years only 5 per cent of the probands and 6.5 per cent of the controls with symptoms, had had sciatica. The curve then increased for

FIG 2 Frequency of Lumbar Spine Syndromes

Sciatica
Lumbago

Low back insufficiency
No clinical history of low back pain

(cf Table 1 Appendix)

distribution was noted. Only 18.8 per cent of the controls stated that they had always been free of symptoms also in other parts of the spine.

Among the probands there was one who in his spontaneous past history omitted to mention previous symptoms of low back disorders. Out of the controls 42 males and 29 females had not had previous symptoms. In the control group the mean age in both males and females was 47.90 ± 2.30 years.

Lumbar spine insufficiency occurred in 17.9 per cent of the probands and in 21.2 per cent of the controls. A statistically significant greater frequency of controls had lumbar spine disorders as compared with the probands ($\chi^2 = 9.07^{**}$, $df = 1$).

Lumbago was found in 53.3 per cent of the probands and in 30.7 per cent of the controls. A comparison of the subjects who merely had symptoms did not reveal any statistically significant differences. In lumbago there was a decided statistically significant surplus of males as compared with female controls ($\chi^2 = 16.94^{***}$, $df = 1$).

Sciatica occurred in 28.3 per cent of the probands and in 14.6 per cent

of the controls. There was no statistically significant difference when comparing the subjects who had symptoms. The distribution of sex revealed a small significant difference ($X^2=4.35$, d.f. = 1) between female and male controls.

Distribution of age

The differences in distribution of age between probands and controls in low back disorders are given in Table 7.

TABLE 7 Age Dependence of Low Back Disorders

		20-29	30-39	40-49	50-59	60-71	20-71
Ins. Insufficiency	P	9 24.2	4 10.5	8 21.0	10 26.3	7 18.0	38 100.0
	C	5 11.1	9 20.0	16 35.6	7 15.6	8 17.7	45 100.0

	C	4 6.2	6 9.2	17 26.2	30 46.1	8 12.3	65 100.0
Sciatica	P	3 5.0	8 13.3	18 30.0	21 35.0	10 16.7	60 100.0
	C	2 6.5	0 —	12 39.0	9 29.0	8 25.5	31 100.0

Low back insufficiency was found to have a high frequency already among the young probands and remained stable after the age of 29 years with the exception of a slight increase in females ranging from 50 to 59 years. In the control subjects the increase continued up to the age group of 40-49 years, after which it rapidly declined.

The frequency of lumbago is comparatively low in the ages from 20-29 years with only 9.7 per cent of probands and 6.2 per cent of controls who had symptoms. There was no increase in the probands belonging to the next decade and only a slight increase in the controls. The highest frequency of lumbago was found in the probands ranging from 40-49 years and 50-59 years in the controls (26.5 per cent and 46.1 per cent, respectively). After the age of 60 years the probands maintained the same figures but the controls revealed a decrease of only 12.3 per cent.

In the ages 20-29 years, only 5 per cent of the probands and 6.5 per cent of the controls with symptoms, had had sciatica. The curve then increased for

the probands in the ages between 50—59 years and for the controls aged 40—49 years. Then a marked decrease was found in both groups.

Hirsch Jonsson *et Leam* (1968) noted the same phenomenon in their female subjects. Due to various selections the series cannot be compared in detail with those of the author.

TABLE 8 Frequency of Low Back Disorders with in the Different Age Groups

		20—29	30—39	40—49	50—59	60—71
Insufficiency	P %	9 39.2	4 17.4	8 14.3	10 28.6	7 18.0
	C %	5 45.4	9 60.0	16 35.5	7 15.2	8 32.2

	C %	4 36.4	6 40.0	17 37.8	30 65.2	8 33.9
Sciatica	P %	3 13.0	8 34.8	18 32.1	21 30.0	10 25.6
	C %	2 18.2	0 —	12 26.7	9 19.6	8 33.9
Total	P %	23 100.0	23 100.0	56 100.0	70 100.0	39 100.0
	C %	11 100.0	15 100.0	45 100.0	46 100.0	24 100.0

On the basis of the number of probands and controls who had symptoms in each age group Table 8 shows in the age group 20—29 years a slightly higher frequency of lumbago as compared to low back insufficiency. In the controls it is the reverse however. Sciatica forms the smallest group among the probands and the controls.

In the age group 30—39 years the number of probands with lumbago was the highest the presence of sciatica was lower and lumbar spine insufficiency occurred least. Controls with symptoms on the other hand had lumbar spine insufficiency in 60 per cent and lumbago in 40 per cent. No control had sciatica in this group. At the ages between 40—49 years the same phenomenon was found among the probands as in the above mentioned group while the controls now had a greater frequency of lumbago as compared to lumbar spine insufficiency. The differences in probands is statistically significant for lumbago as compared with sciatica ($\chi^2=5.25^*$ $df=1$). Sciatica as compared with lumbar spine insufficiency resulted in ($\chi^2=5.01^*$ $df=1$). There was no statistical significance in the controls.

In the age group ranging from 50—59 years lumbago had the greatest frequency in both probands and controls. Sciatica had a lower frequency and lumbar spine insufficiency seldom occurred. The differences between lumbago and sciatica was statistically significant ($\chi^2=9.45^{***}$ d.f.=1) in the probands and ($\chi^2=19.63^{***}$ d.f.=1) in the controls.

In the ages between 60—69 years lumbago had the highest frequency also among the probands followed by a statistically significant lower number of subjects with sciatica ($\chi^2=7.63^{**}$ d.f.=1) and lumbar spine insufficiency ($\chi^2=12.35^{***}$ d.f.=1). In the controls the number of cases of lumbago and sciatica was of the same magnitude with a lowest frequency of lumbar spine insufficiency.

Summary Among the different types of low back pain it was found that the probands had the lowest frequency of lumbar spine insufficiency and the controls the lowest frequency of sciatica. Lumbago was predominant both in the probands and the controls. There was only a statistically significant difference between the probands and the controls in the group of lumbar spine insufficiency with a statistically significant higher number of controls who had symptoms of lumbar spine disorders. More female than male controls had sciatica but on the contrary lumbago was found more often in male than female controls.

The age distribution in the three most common types of lumbar spine disease revealed that the youngest subjects more often had lumbar spine insufficiency than lumbago. The probands aged between 20 and 29 years had a reduced frequency of lumbar spine insufficiency. The same phenomenon was found in the controls in the age group ranging from 30—39 years. The frequency of lumbago increased from 50—59 years of age. Sciatica began with a low frequency in the young group and increased in the probands up to the age group 30—39 years and in the controls in the age group 40—49 years.

The mean age of the probands and the controls who had different types of lumbar spine disorders revealed no statistically significant differences.

Consistent Cases of Lumbar Spine Disorders (see Fig. 3)

Among the subjects with lumbar spine insufficiency consistent cases were found among the probands amounting to 65.8 per cent and among the controls to 91.1 per cent ($\chi^2=8.11^{**}$ d.f.=1). There was a statistically significant greater frequency in male than female controls ($\chi^2=4.59^*$ d.f.=1).

In the group of lumbago a consistent past history was found in 39.8 per cent among the probands and in 81.5 per cent among the controls. A statistically significant greater frequency occurred among the controls ($\chi^2=29.02^{***}$ d.f.=1).

Among the probands there were more males than females who had a consistent past history of lumbago ($\chi^2=6.62^*$ d.f.=1).

In the group of sciatica 33.3 per cent of the probands and 48.4 per cent of

the probands in the ages between 50—59 years and for the controls aged 40—49 years. Then a marked decrease was found in both groups.

Hirsch, Jonsson et Lewin (1968) noted the same phenomenae in their female subjects. Due to various selections the series cannot be compared in detail with those of the author.

TABLE 8 Frequency of Low Back Disorders within the Different Age Groups

		20—29	30—39	40—49	50—59	60—71
Insufficiency	P °	9 39.2	4 17.4	8 14.3	10 28.6	7 18.0
	C °	5 45.4	9 60.0	16 35.5	7 15.2	8 32.2

	C °	4 36.4	6 40.0	17 37.8	30 65.2	8 33.9
Sciatica	P °	3 13.0	8 34.8	18 32.1	21 30.0	10 25.6
	C °	2 18.2	0 —	12 26.7	9 19.6	8 33.9
Total	P °	23 100.0	23 100.0	56 100.0	70 100.0	39 100.0
	C °	11 100.0	15 100.0	45 100.0	46 100.0	24 100.0

On the basis of the number of probands and controls who had symptoms in each age group Table 8 shows in the age group 20—29 years a slightly higher frequency of lumbago as compared to low back insufficiency. In the controls it is the reverse however. Sciatica forms the smallest group among the probands and the controls.

In the age group 30—39 years the number of probands with lumbago was the highest the presence of sciatica was lower and lumbar spine insufficiency occurred least. Controls with symptoms on the other hand had lumbar spine insufficiency in 60 per cent and lumbago in 40 per cent. No control had sciatica in this group. At the ages between 40—49 years the same phenomenon was found among the probands as in the above mentioned group while the controls now had a greater frequency of lumbago as compared to lumbar spine insufficiency. The differences in probands is statistically significant for lumbago as compared with sciatica ($X^2=5.25^*$ d.f.=1). Sciatica as compared with lumbar spine insufficiency resulted in ($X^2=5.01^*$ d.f.=1). There was no statistical significance in the controls.

the controls had a consistent past history of lumbar spine disorders. There were statistically significant more male than female controls ($\chi^2=3.89^*$ d.f.=1).

Within the three groups of lumbar spine disorders consistent past histories were most common in insufficiencies. In sciatica the frequency of consistent cases was the lowest.

The age distribution revealed that consistent cases occurred in a statistically significant greater frequency in the younger subjects (cf Table 2 Appendix). The mean age among those with a consistent past history was 44.95 ± 0.94 years. There was no statistically significant difference between males and females. There were 21 probands and 47 controls with a consistent past history who had had one attack of lumbar spine disorders. On close examination of the probands it was found that five of them had had one attack of sciatica, 15 one attack of lumbago and one had had a longstanding period of low back insufficiency. Out of the controls with one attack, 12 had had insufficiency, 24 lumbago and 11 sciatica. The mean age of the probands was slightly lower than that of the controls and, thus, there was no statistically significant difference. Furthermore the mean age of the entire group with one attack was slightly lower than that of those with a consistent past history on the whole, however without any statistically significant difference.

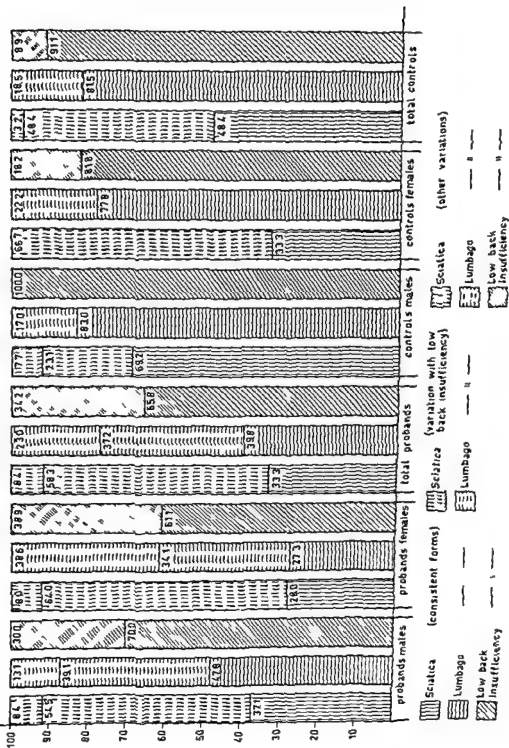

Summary. Consistent cases of the three most common types of low back disorders was found more often among controls than probands. In consistent cases males with sciatica and lumbar spine insufficiency predominated among the controls and with lumbago among the probands.

The age distribution revealed that the youngest, as a rule, had not experienced more than one attack of low back disorders due to their age.

Variation with lumbar spine insufficiency

The most common type of variation is a combination of lumbago and sciatica with low back insufficiency (Fig. 3). A variation of sciatica with low back insufficiency was found in 58.3 per cent of the probands, and in 48.4 per cent of the controls. A statistically significant higher frequency was found among the female controls as compared to the males ($\chi^2=5.74^*$ d.f.=1) but no statistically significant difference between probands and controls. A variation of lumbago with low back insufficiency was found in a statistically significant higher frequency of probands as compared to controls, 37.2 per cent against 18.5 per cent ($\chi^2=6.83^{**}$ d.f.=1). There was no difference in the distribution of sex. Due to the greater number of subjects with lumbago in the entire series variations of sciatica with low back insufficiency are of approximately the same magnitude as variations of lumbago with low back insufficiency. A statistical analysis of the types of lumbar spine syndrome on the other hand, showed a variation with low back insufficiency which was statistically significant more frequent in sciatica than in lumbago ($\chi^2=14.63^{***}$ d.f.=1).

A FIG 3 Consistent Forms and Variation by Different Types of Low Back Disorders

controls had a consistent past history of lumbar spine disorders. There were statistically significant more male than female controls ($\chi^2=3.89^*$ d.f.=1)

Within the three groups of lumbar spine disorders consistent past histories were most common in insufficiencies. In sciatica the frequency of consistent cases was the lowest.

The age distribution revealed that consistent cases occurred in a statistically significant greater frequency in the younger subjects (cf Table 2 Appendix). The mean age among those with a consistent past history was 44.95 ± 0.94 years. There was no statistically significant difference between males and females. There were 21 probands and 47 controls with a consistent past history who had had one attack of lumbar spine disorders. On close examination of the probands it was found that five of them had had one attack of sciatica, 15 one attack of lumbago and one had had a longstanding period of low back insufficiency. Out of the controls with one attack, 12 had had insufficiency, 24 lumbago and 11 sciatica. The mean age of the probands was slightly lower than that of the controls and, thus, there was no statistically significant difference. Furthermore, the mean age of the entire group with one attack was slightly lower than that of those with a consistent past history on the whole, however without any statistically significant difference.

Summary Consistent cases of the three most common types of low back disorders was found more often among controls than probands. In consistent cases males with sciatica and lumbar spine insufficiency predominated among the controls and with lumbago among the probands.

The age distribution revealed that the youngest, as a rule, had not experienced more than one attack of low back disorders due to their age.

Variation with lumbar spine insufficiency

The most common type of variation is a combination of lumbago and sciatica with low back insufficiency (Fig. 3). A variation of sciatica with low back insufficiency was found in 58.3 per cent of the probands and in 48.4 per cent of the controls. A statistically significant higher frequency was found among the female controls as compared to the males ($\chi^2=5.74^*$ d.f.=1) but no statistically significant difference between probands and controls. A variation of lumbago with low back insufficiency was found in a statistically significant higher frequency of probands as compared to controls: 37.2 per cent against 18.5 per cent ($\chi^2=6.83^{**}$ d.f.=1). There was no difference in the distribution of sex. Due to the greater number of subjects with lumbago in the entire series variations of sciatica with low back insufficiency are of approximately the same magnitude as variations of lumbago with low back insufficiency. A statistical analysis of the types of lumbar spine syndrome on the other hand, showed a variation with low back insufficiency which was statistically significant more frequent in sciatica than in lumbago ($\chi^2=14.63^{***}$ d.f.=1).

The subjects who had variations with low back insufficiency were significantly older (mean age 55.38 ± 0.86 years, $t=8.70^{***}$ $df=301$) than those with a consistent past history. Most of them were found in the age group ranging from 50—59 years then the frequency decreased in accordance with the general tendency.

The frequency of variations with lumbar spine insufficiency in this series is close to that reported by Hult (1964, b).

Variations are more often found among the sick listed than those who are not reported sick, especially in the higher age-groups.

Summary Variations with insufficiency have been the cause of most of the recurrences both among probands and controls and appeared in 87 per cent of the subjects complaining of continuous disorders. Variations are more common in probands than in controls. Variations with insufficiency are more frequent in females.

Other types of variation

Other combinations of lumbar disorders occurred more rarely in all the examined groups than variations with low back insufficiency (Fig. 3).

Primary sciatica followed by lumbago occurred in one proband (1.7%) and not in any control. Sciatica followed by lumbago and insufficiency occurred in four probands (6.6%) and in one control (3.2%).

In the subjects with lumbago there was a variation with sciatica in 11 probands (9.7%), a variation with sciatica and insufficiency in 15 probands (13.3%), but in none of the controls. The total amounted to 23 per cent.

In lumbar spine insufficiency, there was a variation with lumbago in 8 probands (21.2%) and in three controls (6.7%). A statistically significant higher frequency of probands as compared to controls with primary insufficiency had variation with lumbago ($X^2=7.34^{**}$ $df=1$). In low back insufficiency there was a variation with sciatica in a slightly lower number five probands (13.1%) and one control (2.2%). The difference is statistically significant ($X^2=4.83^*$ $df=1$).

Similar to lumbago and sciatica varying with insufficiency low back insufficiency with a variation of sciatica had the greatest frequency in the age group 50—59 years. On the other hand, these variations were seldom found before the age of 30 years and after the age of 59 years showed a decided decrease.

One single proband with sciatica had variations with lumbago. On the other hand lumbago as a variation with sciatica occurred much more frequently. Variations with insufficiency were found more often both in the group of sciatica and lumbago than variations with merely sciatica and lumbago respectively.

Lumbago with a variation of sciatica occurred more frequently in probands than controls ($X^2=6.74^{**}$ $df=1$) similar to lumbago with a variation of sciatica and insufficiency ($X^2=9.42^{**}$ $df=1$).

A comparatively high number of subjects with low back insufficiency mostly sick listed had variations with lumbago and sciatica. This frequency is in accordance with earlier investigations (Hult, 1954 b; Hirsch, Jonsson et Lewin 1968).

Summary: In the younger age groups consistency cases of low back syndrome are more common and occur either once only or with few recurrences. With increasing age the number of recurrences augment often as variations with insufficiency. In higher ages almost all the subjects had symptoms of insufficiency irrespective of which type of low back disorders they had at the onset.

5 Age at Onset of Low Back Disorders (See Fig 4)

The figure shows at which age the probands and controls, males and females, had their onset of low back disorders. 29 probands (13.6%) 13 of whom were males and 16 females and ten controls (7.1%) 4 of whom were males and 6 females were subjected to the disease before the age of 20 years.

The onset occurred in 44 probands (16.1%) between 20–29 years of age, 28 of whom were males and 16 females and 47 controls (33.3%) 30 of whom were males and 17 females.

In 56 probands (26.5%) the onset was stated to be at the ages of 30–39 years 37 males and 19 females and in 41 controls (29.1%) 24 males and 17 females.

The age at onset in 50 probands (23.6%) was between 40–49 years 29 of whom were males and 21 females and 24 controls (17.1%) 14 of whom were males and 10 females.

In 27 probands (12.8%) the age at onset was 50–59 years 15 of whom males and 12 females and in 15 controls (10.6%) 11 of whom males and 4 females.

Between the ages of 60–69 years 5 probands (2.4%) had the onset of low back disorders 2 of whom were males and 3 females and 4 controls (2.8%) 1 of whom male and 3 females.

The mean age of 124 male probands was 35.36 ± 1.18 years of 87 female probands 34.77 ± 1.69 years and 84 male controls 34.88 ± 1.75 years and of 57 female controls 34.12 ± 1.83 years.

There is no difference between males and females probands and controls. Statistically significant differences in the age distribution were found only in the ages 20–29 years at which time a significantly larger number of controls than probands were subjected the first time to low back disorders ($\chi^2=14.4***$ df=1). The highest frequency of probands (26.5%) were afflicted with the disease at the age of 30–39 years and the highest frequency of controls (33.3%) at the age of 20–29 years.

Friberg et Hirsch (1949) found that those who had consulted a physician at hospital for commencing low back disorders were frequently aged between 25–

FIG 4 Age of the Onset of Low Back Disorders

29 years Hult (1954) found the same phenomenon in both his investigations. Unander Scharin (1950) in his series found that 4 per cent of the cases had the onset before the age of 20 years and 56 per cent at the age of 20—29 years.

6 Recurrences

Out of those who had previous symptoms 21 probands (10 %) and 47 controls (33.3 %) had merely one attack of lumbar spine disorders. Recurring lumbar spine disorders were found in 190 probands and in 94 controls with a statistically significant higher frequency of the probands ($\chi^2 = 29.64^{***}$ d.f. = 1). Recurrences occurred according to the following Table.

TABLE 9 Recurrences

Two attacks of low back pain	29 probands	6 controls	35
Three	6	8	14
Four	11	2	13
Five	10	5	15
Six " "	8	4	12
Seven " "	3	1	4
Eight " " "	2	1	3
More or persisting	121	67	188
Total	190	94	284

Table 9 shows that the majority of both probands and controls had continual low back disorders.

Table 10 shows the recurrences according to distribution of sex and age and also the number of probands and controls with recurrences. The figures in brackets indicate subjects who had one attack of lumbar spine disorders.

A higher number of probands had recurrences earlier than the controls. Already at the age of 29 years 36.4 per cent males and 75 per cent females had recurrences as compared to 25 per cent male and 57.1 per cent female controls.

At the age of 42 years nearly all the probands had had recurrences while the controls experienced the same 20 years later.

It was also found with slight exceptions that with increasing age the frequency of recurrences became higher in the series. The mean age of those who had one attack of low back disorders is statistically significant lower than that of those with recurrences, with the exception of female probands (Table 2 Appendix).

At the time of examination in 1967 it was found that subjects who had been examined and found to have had one attack of low back disorders were 22 years

TABLE 10
Recurrences according to Distribution of Age and Sex

Age	Probands				Controls			
	Males	°.	Females	°.	Males	°.	Females	°.
20-29	4	36.4 (7)	9	75.0 (3)	1	25.0 (3)	4	57.1 (3)

60-69	24	96.0 (1)	13	100.0 (0)	11	84.6 (2)	11	100.0 (0)
70-	0	— (0)	1	100.0 (0)	0	— (0)	0	— (0)
Total	111	(13)	79	(8)	48	(35)	46	(12)

	Males	Females	Males	Females
Mean age With recurrences	51.03 ± 1.01	48.22 ± 1.38	51.45 ± 1.44	49.78 ± 12.06 years
One attack of low back pain	37.31 ± 3.15	42.50 ± 5.26	47.57 ± 1.80	40.83 ± 6.21 years

trically significant free of symptoms more often than those who had had recurrences ($\chi^2=20.62^{***}$ d f = 1) in probands and ($\chi^2=44.33^{***}$ d f = 1) in controls. Contrary to this there were statistically significant more probands and controls with symptoms at the time of examination in the group who had had recurrences ($\chi^2=13.62^{***}$ d f = 1) and ($\chi^2=52.13^{***}$ d f = 1) respectively.

Subjects with frequent periods of symptoms were given special attention. The cases of recurrences were classified in two groups: those with a small number of recurrences and those with eight or more attacks. The distribution of age and sex however showed slight differences with a tendency to a higher mean age of those with fewer recurrences except for the female controls where the differences was statistically significant (Table 2 Appendix).

Recurring attacks of low back pain occurred significantly more frequently in probands than in controls. The recurrences depended on the age among the controls and increased to 40-49 years among the probands. Those who in their early years had had an attack of low back pain stood a greater chance of having recurrences later on. Those with low back disorders who were forced to report themselves sick at an early stage consequently risk having more

attacks in the future. Not only recurrences were expected but also the number of attacks would depend on the age. The investigation revealed that this only happened up to a certain number of recurrences. Those who had nine or more attacks of low back disorders were not any older than those with a lower number of recurrences. This may be explained by the fact that those who had nine or more attacks of low back disorders had a different type of low back pain viz lumbar spine insufficiency.

7 Duration of Symptoms

TABLE 11 Duration of Symptoms

1 week	1-4 weeks	4 weeks-6 months	6 months-1 year	More
P 36.8%	30.5%	28.2%	4%	0.5%
C 76.7%	15.1%	5.8%	2.4%	—

N = 190 Probands and 94 Controls

(χ^2 equals duration of symptoms less than one week 36.77*** d.f. = 1 duration of symptoms less than four weeks 18.80*** d.f. = 1)

A statistically significant higher frequency of controls had a short duration of low back disorders on several occasions as compared with the probands.

At the first attack the low back disorders lasted for a short time but the difference between the duration of the first attack and the duration of the recurrences was not statistically significant.

8 Individual Opinions as to Causes of Symptoms

The subjects were asked to give their opinion on the cause of the onset and the recurrences of low back disorders. At the investigation in 1967, 27.9 per cent of the probands and 23.4 per cent of the controls believed that the first symptoms were the result of an accident. 27.4 per cent of the probands and 24.1 per cent of the controls had received symptoms after heavy lifting. True accidents from the legal point of view as a cause of the onset were verified by a higher frequency of probands. The difference is not statistically significant. Rarely was trauma stated as the cause of recurrences. The probands stated trauma in 21.6 per cent and heavy lifting in 23.2 per cent, the controls mentioned trauma in 10.6 per cent and heavy lifting in 20.2 per cent.

A statistically significant higher frequency of probands than controls had recurrences following an accident ($\chi^2 = 7.32^{**}$ d.f. = 1).

At an attack of low back pain around 1964 the value obtained was ($\chi^2 = 8.24^{**}$ d.f. = 1) at the examination in 1967 ($\chi^2 = 9.31^{**}$ d.f. = 1).

TABLE 10
Recurrences according to Distribution of Age and Sex

One attack of low back pain	37.31 ± 3.15	42.50 ± 5.26	47.57 ± 1.80	40.83 ± 6.21 years

tically significant free of symptoms more often than those who had had recurrences ($\chi^2=20.62^{***}$ d f = 1) in probands and ($\chi^2=44.33^{***}$ d f = 1) in controls. Contrary to this there were statistically significant more probands and controls with symptoms at the time of examination in the group who had had recurrences ($\chi^2=13.62^{***}$ d f = 1) and ($\chi^2=52.13^{***}$ d f = 1) respectively.

Subjects with frequent periods of symptoms were given special attention. The cases of recurrences were classified in two groups: those with a small number of recurrences and those with eight or more attacks. The distribution of age and sex however showed slight differences with a tendency to a higher mean age of those with fewer recurrences except for the female controls where the differences was statistically significant (Table 2 Appendix).

Recurring attacks of low back pain occurred significantly more frequently in probands than in controls. The recurrences depended on the age among the controls and increased to 40-49 years among the probands. Those who in their early years had had an attack of low back pain stood a greater chance of having recurrences later on. Those with low back disorders who were forced to report themselves sick at an early stage consequently risk having more

attacks in the future. Not only recurrences were expected, but also the number of attacks would depend on the age. The investigation revealed that this only happened up to a certain number of recurrences. Those who had nine or more attacks of low back disorders were not any older than those with a lower number of recurrences. This may be explained by the fact that those who had nine or more attacks of low back disorders had a different type of low back pain viz lumbar spine insufficiency.

7 Duration of Symptoms

TABLE 11 Duration of Symptoms

1 week	1—4 weeks	4 weeks—6 months	6 months—1 year	More
T 36.8%	30.5%	28.2%	4%	0.5%
C 76.7%	15.1%	5.8%	2.4%	—

N = 193 Probands and 94 Controls

(χ^2 equals duration of symptoms less than one week 36.77*** d.f. = 1 duration of symptoms less than four weeks 18.80*** d.f. = 1)

A statistically significant higher frequency of controls had a short duration of low back disorders on several occasions as compared with the probands.

At the first attack the low back disorders lasted for a short time, but the difference between the duration of the first attack and the duration of the recurrences was not statistically significant.

8 Individual Opinions as to Causes of Symptoms

The subjects were asked to give their opinion on the cause of the onset and the recurrences of low back disorders. At the investigation in 1967 27.9 per cent of the probands and 23.4 per cent of the controls believed that the first symptoms were the result of an accident. 27.4 per cent of the probands and 24.3 per cent of the controls had received symptoms after heavy lifting. True accidents from the legal point of view as a cause of the onset were verified by a higher frequency of probands. The difference is not statistically significant. Rarely was trauma stated as the cause of recurrences. The probands stated trauma in 21.6 per cent and heavy lifting in 23.7 per cent, the controls mentioned trauma in 10.6 per cent and heavy lifting in 20.2 per cent.

A statistically significant higher frequency of probands than controls had recurrences following an accident ($\chi^2 = 7.32^{**}$ d.f. = 1).

At an attack of low back pain around 1964 the value obtained was ($\chi^2 = 8.24^{**}$ d.f. = 1) at the examination in 1967 ($\chi^2 = 9.31^{**}$ d.f. = 1).

A statistically significant higher frequency of controls than probands explained the symptoms occurring spontaneously at the onset ($\chi^2 = 11.36^* \text{ df} = 4$) and at the recurrences ($\chi^2 = 10.40^* \text{ df} = 4$)

A supposition that low back pain resulting from an accident should be of a more intense kind was not verified in this series. A statistically significant higher frequency of controls merely revealed more often intense pain than slight at the onset after an accident ($\chi^2 = 22.45^{***} \text{ df} = 1$). In recurrences there was no difference between probands and controls in this respect. For further details see separate Table 5.

Pain/ache in the low back due to coughing or sneezing in different diagnoses see separate Table 6.

Summary. Accidents and heavy lifting interpreted by the subjects as the cause of low back disorders predominated in the probands from the onset and at the recurrences up to the time of examination. The differences are difficult to explain by the selection and probably depend on lapse of memory.

9 Distribution of Lumbar Spine Diagnoses on Examination in 1967

On the basis of symptoms and signs at the examination in 1967 each proband and control was classified in Diagnostic Groups. Belonging to Group 1 were subjects who had no symptoms and no pathological findings of importance. In Group 2 were included the subjects who had no symptoms but severe restriction of mobility in the lumbar spine. Those classified in Group 3 had symptoms of tiredness, weakness, sensation of stiffness or dull pain in the lumbar spine radiating, feeling of discomfort only if the radiation was not of a radicular kind and previously defined as lumbar spine insufficiency. The findings were either quite negative or else there were only insignificant clinical findings such as tenderness on palpation of a spinal process or pain where there was no contraction in the paravertebral musculature either in a recumbent or standing position. Group 4 included subjects with lumbago who had severe pain/ache, contraction of musculature, severe restriction of mobility and tenderness in most of the cases. Lasègue's sign was positive. Group 5 contained subjects with radiating pain of a radicular kind (sciatica without positive Lasègue's sign and no neurological disturbances). The subjects in Group 6 had sciatica with positive Lasègue's sign but no neurological disturbances. In Group 7 the subjects had sciatica with positive Lasègue's sign and neurological disturbances.

In Group 1 there were 96 probands and 147 controls. The number of controls was statistically significant higher than the number of probands ($\chi^2 = 25.07^{***} \text{ df} = 1$). A statistically significant higher frequency of controls can be explained by the selection and the actual definition of the control group.

In Group 2 there were 3 probands and 6 controls, all of whom had a high mean age (Table 3, Appendix) with the exception of one female control. The

high mean age probably is the explanation of the restricted mobility in the lumbar spine

In Group 3 there were 98 probands and 58 controls. A statistically significant greater number of probands was found as compared to controls ($\chi^2=6.99^{**}$ $df=1$). A statistically significant higher number of females was found both among the probands and the controls ($\chi^2=6.50^*$ $df=1$) in probands and ($\chi^2=6.59^*$ $df=1$) in controls. The mean age in Group 3 was similar to that of Group 1.

In Group 4 there were only 3 probands. None belonged to Group 5. In Group 6 there were 6 probands and in Group 7 there were 6 probands and one female control.

Table 12 Examination in 1967. Subjects without and with Symptoms Without Symptoms (Diagnostic Groups 1—2)

	Probands		Controls

during a long period of time could be of prognostic value. A time analysis concerning the history of pain of the subject from the onset until the examination in 1967 therefore, was carried out.

The table shows that 81.3 per cent of the probands without symptoms at the examination (Groups 1—2) had had recurrences while the probands in Group 3 had had recurrences in 97.9 per cent. The difference is highly significant ($\chi^2 = 10.38$ * d.f. = 1).

Out of the controls without symptoms a total of 70 per cent had recurrences and out of 58 controls in Group 3 recurrences occurred in 91.4 per cent. The difference is statistically highly significant ($\chi^2 = 30.01^{***}$ d.f. = 1).

All the subjects in Groups 4, 6 and 7 had recurrences between the onset and up to the time of examination.

In order to investigate the pain syndrome of the probands and the controls at the examination and to study any possibilities of analysing the limits between different types of lumbar spine insufficiency, Table 14 below was compiled.

Only 34 probands and 14 controls had earlier had quite symptom free intervals between periods of lumbago or sciatica. Contrary to this 36 probands and 46 controls had continual spinal symptoms of the insufficiency type. 12 probands of whom one and one control had variations with sciatica. The others either had attacks of slight symptoms occurring merely in connection with strain or slight attacks however without any special stress in the spine. The patients were rather vague in their answers, and found it difficult to give exact answers to the

On the basis of previous definitions, the two first groups of diagnoses were combined to involve subjects without symptoms with or without clinical signs. The groups of diagnoses 3—7 included subjects with symptoms with or without clinical signs.

The subjects without symptoms (Groups 1 and 2) amounted to 46.7 per cent of all the probands and 72.2 per cent of the controls and those with existing symptoms (Groups 3—7) amounted to 53.3 per cent of the probands and 27.8 per cent of the controls (Table 12). There was a statistically significant greater number of probands than controls who at the examination in 1967 had symptoms of lumbar spine disorders ($X^2=25.21^{***}$ d.f. = 1).

In 15 probands and one control there was acute lumbago or sciatica ($X^2=38.43^{***}$ d.f. = 1).

10 Correlation between Various Types of Low Back Disorders and Classification of Diagnoses on Examination in 1967

Table 12 shows the relation between retrospectively interpreted types of low back symptoms and existing symptoms on examination in 1967. 47.3 per cent of the probands and controls from the group of sciatica and 63.5 per cent of the group of lumbago were at the time of examination free of symptoms but only 28.9 per cent from the group of insufficiency. A statistically significant greater frequency of the subjects with previous lumbago had no symptoms in 1967 as compared to those with sciatica ($X^2=6.51^*$ d.f. = 1). The statistically significant lowest number of probands and controls without symptoms belonged to the group with low back insufficiency as compared both with sciatica ($X^2=6.16^*$ d.f. = 1) and lumbago ($X^2=27.12^{***}$ d.f. = 1). At the examination there were both among the probands and the controls significantly more males without symptoms as compared to females: probands ($X^2=8.36^{**}$ d.f. = 1) and controls ($X^2=5.31^*$ d.f. = 1).

Most of the subjects without symptoms at the time of examination belonged to the group of consistent cases in sciatica 60.5 per cent, lumbago 66.4 per cent and insufficiency 85.8 per cent.

Summary. At the examination in 1967 it was mostly found that subjects in the group of lumbago had no symptoms. Those with insufficiency had the most pronounced symptoms. The consistent cases of low back disorders more often had no symptoms than those with variations. Males were more often than females free of symptoms.

History of pain in various groups of lumbar spine diagnosis

The question arose whether the various groups of diagnosis at the investigation in 1967 were classified at random and whether the same series representative

Table 12 shows the relation between retrospectively interpreted types of low back symptoms and existing symptoms on examination in 1967. 47.3 per cent of the probands and controls from the group of sciatica and 63.5 per cent of the group of lumbago were at the time of examination free of symptoms but only 28.9 per cent from the group of insufficiency. A statistically significant greater frequency of the subjects with previous lumbago had no symptoms in 1967 as compared to those with sciatica ($\chi^2=6.51^*$ d.f.=1). The statistically significant lowest number of probands and controls without symptoms belonged to the group with low back insufficiency as compared both with sciatica ($\chi^2=6.16^*$ d.f.=1) and lumbago ($\chi^2=27.12^{***}$ d.f.=1). At the examination there were both among the probands and the controls significantly more males without symptoms as compared to females: probands ($\chi^2=8.36^{**}$ d.f.=1) and controls ($\chi^2=5.31^*$ d.f.=1).

Most of the subjects without symptoms at the time of examination belonged to the group of consistent cases: in sciatica 60.5 per cent, lumbago 66.4 per cent and insufficiency 85.8 per cent.

Summary. At the examination in 1967 it was mostly found that subjects in the group of lumbago had no symptoms. Those with insufficiency had the most pronounced symptoms. The consistent cases of low back disorders more often had no symptoms than those with variations. Males were more often than females free of symptoms.

History of pain in various groups of lumbar spine diagnosis

The question arose whether the various groups of diagnosis at the investigation in 1967 were classified at random and whether the same series representative

Table 4 (cf Table Appendix) shows that the onset of cervical spine symptoms occurs almost simultaneously with the onset of low back disorders but the mean age is slightly higher. Thus it can be assumed that the onset of cervical spine disorders as a rule occurs six years later than that of low back disorders. The age at onset of thoracic spine disorders is close to that of the lumbar spine, and the difference is not important as regards the mean age (cf Table 5, Appendix).

Wry neck and brachialgia

Wry neck syndrome had occurred before the examination in 1967 in 16.5 per cent of the probands and in 14.2 per cent of the controls. Wry neck and brachialgia was found in 30.9 per cent of the probands and 25.4 per cent of the controls mentioned above. At the examination in 1967 42.3 per cent of the probands and 37.5 per cent of the controls had brachialgia with cervical spine disorders. The high percentage may be explained by the comparatively low number of examined subjects with existing cervical spine disorders.

Incidence of thoracic spine syndromes with/without radiating pain

Radiating pain in subjects who earlier had thoracic spine symptoms were rarely found. Only 9.7 per cent of the probands and 11.3 per cent of the controls with symptoms had stated in their past history that they had had thoracic spine syndrome with radiating pain.

Similar to the lumbar spine it proved necessary to differentiate between various types of symptoms also in the cervical and thoracic spine. The same definitions as for the lumbar spine, namely, intense and slight pain/ache have been employed. Insufficiency of the cervical and thoracic spine was defined as a sensation of tiredness, weakness, stiffness and dull pain, assessing the intensity of the pain, its duration and relation to the strain. Cervical and thoracic spine symptoms were classified in cases with singular attacks with/without radiating pain (thoracic and cervical spine syndrome with/without radiating pain) and in cervical and thoracic spine insufficiency only. Table 6 in the Appendix shows that insufficiency occurs more often than singular attacks. There was only a statistically significant difference in a combination of cervical and thoracic spine syndrome in the above described types. In the probands ($\chi^2=16.67^{***}$ d.f.=1) in the controls ($\chi^2=27.52^{***}$ d.f.=1).

For further details see separate Tables 7-14.

12 Correlation between Different Locations of Spinal Pain

Table 6 in the Appendix indicates various types of cervical and thoracic syndromes. Some frequencies are too low to allow statistical analysis.

Various types of cervical and thoracic spine symptoms mostly occurred in subjects with lumbar spine insufficiency (71.1% probands and 68.9% controls 70.4% of whom were the earlier mentioned probands and 93.5% were the

TABLE 14 Analysis of Pain Syndrome on Examination in 1967

	P				C				P				C

questions posed. The subject's hesitance with respect to the term strain was also remarkable and very diffuse. It seems impossible to draw limits between past histories which can serve as a type for further classification of lumbar spine insufficiency.

11 Incidence of Cervical and Thoracic Pain

A common idea is that the spine on the whole is a functional unit. At the examination in 1967 existing cervical and thoracic spine symptoms therefore, were also given attention. It was found that 107 probands (50.5%) and 81 controls (38.2%) had had earlier symptoms in the cervical spine. The number of probands was significantly higher than that of the controls ($\chi^2=5.88$, $df=1$). 49 probands (23.1%) and 38 controls (17.9%) complained of previous symptoms in the thoracic spine. The difference is not statistically significant. Symptoms in both the cervical and thoracic spine were present in 27 probands (12.7%) and in 24 controls (11.3%). Out of the above mentioned subjects with cervical spine symptoms 81 probands (75.7%) and 59 controls (72.6%) had recurring symptoms. 36 probands (73.5%) and 24 controls (63.2%) had recurring thoracic spine symptoms.

At the time of examination in 1967 26 probands (12.3%) and 16 controls (7.5%) had cervical spine symptoms. 7 probands (3.3%) and 5 controls (2.4%) had thoracic spine symptoms. There were no statistically significant differences between probands and controls. Most of the subjects who were examined had the onset of cervical spine symptoms at the ages ranging from 30–49 years while 6 probands and 5 controls had experienced symptoms before the age of 20 years.

Table 4 (cf Table Appendix) shows that the onset of cervical spine symptoms occurs almost simultaneously with the onset of low back disorders but the mean age is slightly higher. Thus it can be assumed that the onset of cervical spine disorders as a rule occurs six years later than that of low back disorders. The age at onset of thoracic spine disorders is close to that of the lumbar spine and the difference is not important as regards the mean age (cf Table 5 Appendix).

Wry neck and brachialgia

Wry neck syndrome had occurred before the examination in 1967 in 16.5 per cent of the probands and in 14.2 per cent of the controls. Wry neck and brachialgia was found in 30.9 per cent of the probands and 25.4 per cent of the controls mentioned above. At the examination in 1967 42.3 per cent of the probands and 37.5 per cent of the controls had brachialgia with cervical spine disorders. The high percentage may be explained by the comparatively low number of examined subjects with existing cervical spine disorders.

Incidence of thoracic spine syndromes with without radiating pain

Radiating pain in subjects who earlier had thoracic spine symptoms were rarely found. Only 9.7 per cent of the probands and 11.3 per cent of the controls with symptoms had stated in their past history that they had had thoracic spine syndrome with radiating pain.

Similar to the lumbar spine it proved necessary to differentiate between various types of symptoms also in the cervical and thoracic spine. The same definitions as for the lumbar spine namely intense and slight pain/ache have been employed. Insufficiency of the cervical and thoracic spine was defined as a sensation of tiredness, weakness, stiffness and dull pain, assessing the intensity of the pain, its duration and relation to the strain. Cervical and thoracic spine symptoms were classified in cases with singular attacks with/without radiating pain (thoracic and cervical spine syndrome with/without radiating pain) and in cervical and thoracic spine insufficiency only. Table 6 in the Appendix shows that insufficiency occurs more often than singular attacks. There was only a statistically significant difference in a combination of cervical and thoracic spine syndrome in the above-described types. In the probands ($\chi^2=16.67^{***}$ d.f.=1) in the controls ($\chi^2=27.52^{***}$ d.f.=1).

For further details see separate Tables 7-14.

12 Correlation between Different Locations of Spinal Pain

Table 6 in the Appendix indicates various types of cervical and thoracic syndromes. Some frequencies are too low to allow statistical analysis.

Various types of cervical and thoracic spine symptoms mostly occurred in subjects with lumbar spine insufficiency (71.1% probands and 68.9% controls 70.4% of whom were the earlier mentioned probands and 93.5% were the

earlier mentioned controls with cervical and thoracic syndromes of the insufficiency type) A statistically significant higher frequency of the controls had cervical and thoracic symptoms of the insufficiency type ($X^2 = 5.43^* \text{ d.f.} = 1$)

Symptoms in the cervical and thoracic spine were found in 56.7 per cent of the probands with sciatica as the initial disease, 64.7 per cent of whom had insufficiency. In the control series there was only 32.3 per cent, 80 per cent of whom had insufficiency. A statistically significant higher frequency of probands than of controls had symptoms in the cervical and thoracic spine in this group ($X^2 = 4.88^* \text{ d.f.} = 1$). Insufficiency was more common among the controls.

The probands with lumbago had symptoms in the cervical and thoracic spine in 60.2 per cent, 55.9 per cent of whom had insufficiency. A statistically significant lower number of controls (35.4 %) had the same combination ($X^2 = 10.15^{***} \text{ d.f.} = 1$).

Summary Combinations of lumbar spine syndrome with symptoms in the cervical and thoracic spine were commonly found in the group with lumbar spine insufficiency. The cases of insufficiency were in the majority in this group. Most combinations with cervical and thoracic symptoms occurred among the variations with lumbar spine insufficiency and these groups included the highest frequency of insufficiency of other parts of the spine. A lower number of controls had symptoms in the cervical and thoracic spine as compared to the probands. On the other hand in the group with sciatica and lumbar spine insufficiency the controls were found to have a comparatively greater frequency of insufficiency in the cervical and thoracic spine than the probands. More females than males had symptoms in the cervical and thoracic spine and insufficiency was predominant in the females. The differences could however not be statistically analysed due to the low frequency.

In order to analyse the subjects from the prognostic point of view they were classified in groups according to which part of the spine the disease had set in. Probands with lumbar spine insufficiency and variations in lumbar spine insufficiency more often had cervical and thoracic spine disturbances of the insufficiency type and formed a prognostically demarcated group. When probands with lumbar spine insufficiency or variation with lumbar spine insufficiency who had also had cervical or thoracic spine insufficiency were compared with the other probands belonging to the same series the following results were obtained (Table 7 Appendix).

Probands with spine insufficiency had statistically significant more recurrences of lumbar spine symptoms and more often lumbar spine symptoms at the examination in 1967 and also significantly more often symptoms in all three parts of the spine as compared to other probands. The mean number of sick listing periods and sick list days was higher in the group with insufficiency. Despite the difference not being statistically significant it is still important due to the fact that the series taken from the National Health Insurance Society only

date from the time after 1955 which is too short a period to allow probands with several recurrences to exhibit significant differences. Probands with lumbar spine insufficiency or variations of lumbar spine insufficiency combined with insufficiency symptoms in the cervical or thoracic spine form a significantly inferior group from the prognostic point of view, as compared to the other subjects examined.

Summary of various types of spinal disorders

Lumbago is the most frequently occurring lumbar spine disease. Lumbar spine insufficiency was rarely found in the probands and sciatica in the controls. There was a statistically significant higher number of controls as compared to probands who had lumbar spine insufficiency of a consistent type. It was more common with one attack of lumbar spine symptoms among the controls than among the probands. At the examination in 1967 the consistent cases were more often free of symptoms than those who had variations. They also had less recurrences. On the other hand the probands more often had variations with insufficiency than consistent types of lumbar spine symptoms, a higher frequency of symptoms at the time of examination and more recurrences. This phenomenon would explain their reason for consulting a physician with sick listing as a result.

Females more often than males had lumbar spine insufficiency more symptoms from the cervical and thoracic spine and frequently they had symptoms at the time of examination in 1967. The combination of lumbar spine disorders with cervical and thoracic spine syndrome was more often found in the probands with the exception of the group with lumbar spine insufficiency in which the controls more often had symptoms of insufficiency in the cervical and thoracic spine. The probands who besides lumbar spine insufficiency or variations with lumbar spine insufficiency also had symptoms of insufficiency in the cervical or thoracic spine had a statistically significant higher rate of recurrences as a rule, persisting symptoms also at the time of examination in 1967. The number of sick days and sick periods was higher than for the other probands.

In the young age-groups lumbar spine insufficiency was most common. Later lumbago set in and became predominant while sciatica developed later still and progressed with increasing age up to 59 years. The youngest subjects in the series were those who had one attack of lumbar spine disorders followed by those with consistent types. Variations of lumbar spine disorders were most common in the highest age groups.

13 Clinical Findings at Examination

Configuration of the spine

Table 8 in the Appendix shows the clinical changes of configuration in the cervical, thoracic and lumbar spine. Normal cervical spine was found in 99.5

earlier mentioned controls with cervical and thoracic syndromes of the insufficiency type) A statistically significant higher frequency of the controls had cervical and thoracic symptoms of the insufficiency type ($X^2 = 5.43^* \text{ d.f.} = 1$)

Symptoms in the cervical and thoracic spine were found in 56.7 per cent of the probands with sciatica as the initial disease 64.7 per cent of whom had insufficiency In the control series there was only 32.3 per cent 80 per cent of whom had insufficiency A statistically significant higher frequency of probands than of controls had symptoms in the cervical and thoracic spine in this group ($X^2 = 4.88^* \text{ d.f.} = 1$) Insufficiency was more common among the controls

The probands with lumbago had symptoms in the cervical and thoracic spine in 60.2 per cent 55.9 per cent of whom had insufficiency A statistically significant lower number of controls (35.4 %) had the same combination ($X^2 = 10.15^{***} \text{ d.f.} = 1$)

Summary Combinations of lumbar spine syndrome with symptoms in the cervical and thoracic spine were commonly found in the group with lumbar spine insufficiency The cases of insufficiency were in the majority in this group Most combinations with cervical and thoracic symptoms occurred among the variations with lumbar spine insufficiency and these groups included the highest frequency of insufficiency of other parts of the spine A lower number of controls had symptoms in the cervical and thoracic spine as compared to the probands On the other hand in the group with sciatica and lumbar spine insufficiency the controls were found to have a comparatively greater frequency of insufficiency in the cervical and thoracic spine than the probands More females than males had symptoms in the cervical and thoracic spine and insufficiency was predominant in the females The differences could however not be statistically analysed due to the low frequency

In order to analyse the subjects from the prognostic point of view they were classified in groups according to which part of the spine the disease had set in Probands with lumbar spine insufficiency and variations in lumbar spine insufficiency more often had cervical and thoracic spine disturbances of the insufficiency type and formed a prognostically demarcated group When probands with lumbar spine insufficiency or variation with lumbar spine insufficiency who had also had cervical or thoracic spine insufficiency were compared with the other probands belonging to the same series the following results were obtained (Table 7 Appendix)

Probands with spine insufficiency had statistically significant more recurrences of lumbar spine symptoms and more often lumbar spine symptoms at the examination in 1967 and also significantly more often symptoms in all three parts of the spine as compared to other probands The mean number of sick listing periods and sick list days was higher in the groups with insufficiency Despite the difference not being statistically significant it is still important due to the fact that the series taken from the National Health Insurance Society only

date from the time after 1955 which is too short a period to allow probands with several recurrences to exhibit significant differences. Probands with lumbar spine insufficiency or variations of lumbar spine insufficiency combined with insufficiency symptoms in the cervical or thoracic spine, form a significantly inferior group from the prognostic point of view, as compared to the other subjects examined.

Summary of various types of spinal disorders

Lumbago is the most frequently occurring lumbar spine disease. Lumbar spine insufficiency was rarely found in the probands and sciatica in the controls. There was a statistically significant higher number of controls as compared to probands who had lumbar spine insufficiency of a consistent type. It was more common with one attack of lumbar spine symptoms among the controls than among the probands. At the examination in 1967 the consistent cases were more often free of symptoms than those who had variations. They also had less recurrences. On the other hand the probands more often had variations with insufficiency than consistent types of lumbar spine symptoms, a higher frequency of symptoms at the time of examination and more recurrences. This phenomenon would explain their reason for consulting a physician with sick listing as a result.

Females more often than males had lumbar spine insufficiency, more symptoms from the cervical and thoracic spine and frequently they had symptoms at the time of examination in 1967. The combination of lumbar spine disorders with cervical and thoracic spine syndrome was more often found in the probands with the exception of the group with lumbar spine insufficiency in which the controls more often had symptoms of insufficiency in the cervical and thoracic spine. The probands who besides lumbar spine insufficiency or variations with lumbar spine insufficiency also had symptoms of insufficiency in the cervical or thoracic spine had a statistically significant higher rate of recurrences as a rule, persisting symptoms also at the time of examination in 1967. The number of sick days and sick periods was higher than for the other probands.

In the young age groups lumbar spine insufficiency was most common. Later lumbago set in and became predominant while sciatica developed later still and progressed with increasing age up to 59 years. The youngest subjects in the series were those who had one attack of lumbar spine disorders followed by those with consistent types. Variations of lumbar spine disorders were most common in the highest age groups.

13 Clinical Findings at Examination

Configuration of the spine

Table 8 in the Appendix shows the clinical changes of configuration in the cervical, thoracic and lumbar spine. Normal cervical spine was found in 99.5

per cent Normal thoracic spine was noted in 71.7 per cent of the probands and 73.6 per cent of the controls. In the lumbar spine the corresponding figures were 73.6 per cent in the probands and 75 per cent in the controls. Slightly more normal thoracic spines were found in the controls who previously had not had symptoms in the lumbar spine as compared to those with earlier symptoms.

Scoliosis of the thoracic spine was noted in 9.4 per cent of the probands and 9.8 per cent of the controls and of the lumbar spine in 8 per cent of the probands and 8.9 per cent of the controls. No differences were observed between those with earlier lumbar spine syndrome and those without previous symptoms. Nor were there any differences between those who at the examination were free of symptoms and those who had symptoms. Consequently in this series changes of configuration cannot be regarded as the cause of spinal disorders of the type to which this investigation refers.

Painful palpation over spinal process

Table 9 in the Appendix shows the rate of painful palpation over the spinal process in different parts of the spine. Painful palpation refers to percussive tenderness with superficial or deep pain in one or several vertebrae and not in the musculature. This phenomenon was not often found. It was more common in the cervical spine, but rare in the spinal processes of the thoracic vertebrae. In the cervical- and lumbar spine the symptom was observed statistically significant more often in the probands than in the controls ($\chi^2 = 11.4^{***}$ d.f. = 1) for lumbar spine and ($\chi^2 = 9.63^{**}$ d.f. = 1) for cervical spine. The frequency was low and without significant differences in the thoracic spine. There was a greater number of probands with lumbar spine symptoms who had percussive tenderness in the cervical spine as compared to those who had no symptoms at the examination ($\chi^2 = 9.81^{**}$ d.f. = 1).

Besides differences between the probands and the controls who at the examination either were free of symptoms or else had symptoms, the controls with earlier symptoms had significantly more often tenderness in the lumbar spinal processes as compared to those without symptoms ($\chi^2 = 4.19^*$ d.f. = 1). A comparison between probands and controls without and with symptoms revealed ($\chi^2 = 15.74^{***}$ d.f. = 1) and ($\chi^2 = 9.21^{**}$ d.f. = 1) respectively.

Summary Painful palpation over the spinal process is significantly more common in probands than in controls. The same observation was made when subjects with earlier symptoms were compared with those without symptoms and with subjects who had existing lumbar spine disorders. Almost the same phenomenon was found with respect to the cervical spine in probands and controls who either had or had not lumbar spine disorders. It is plausible that the onset of cervical spine symptoms in subjects with lumbar spine symptoms could point to a non-differentiated spinal disease. The low frequency of subjects

complaining of tenderness on palpation of the snail process and the fact that the assessment is subjective demands a certain amount of reservation with regard to the clinical value of this symptom

Function of the spine (Table 10 Appendix)

The series was classified in different spinal groups: normal mobility, slight fixation, severe fixation and stiffness. As a criterion on normal function was regarded symmetrical mobility of the spine in different directions without pain or muscular strain as the definition of mobility is difficult to state in degrees varies in different subjects and also depends on their age. Slight and severe fixation of the spine could be determined by the author on the basis of deviations from the normal function.

Normal mobility of the cervical spine occurred in 74.1 per cent of the probands and in 80.2 per cent of the controls. No differences were found between controls with earlier spinal symptoms and those without symptoms.

Controls without symptoms at the examination had a statistically significant greater frequency of normal mobility in the cervical spine as compared to the controls with lumbar spine syndrome ($\chi^2 = 10.21^{***}$ d.f. = 1).

The mobility of the thoracic spine in 99 per cent of the controls and in 98.6 per cent of the probands was normal and the same figures applied to the other groups without any statistically significant difference being noted.

In the lumbar spine there was normal mobility in 81.6 per cent of the probands and in 95.8 per cent of the controls. The difference is statistically significant ($\chi^2 = 21.14^{***}$ d.f. = 1) and can be explained by a greater frequency of slight fixation of the lumbar spine in the group of probands. As has earlier been pointed out in the analysis of Group 2 the difference is found in the higher mean age of probands with a stiffer lumbar spine. Slight fixation of the lumbar spine was found in a significantly greater number of subjects who had symptoms at the examination in 1967 as compared to those without symptoms. The probands thus had ($\chi^2 = 22.04^{***}$ d.f. = 1) and the controls ($\chi^2 = 8.32^{**}$ d.f. = 1). Severe fixation of the lumbar spine occurred to a greater extent at the examination of probands with symptoms (5.3%) than of those without symptoms (3%) and in one of the controls with symptoms (1.7%). Stiff lumbar spine was found in two probands with symptoms at the examination (1.8%).

Summary. Reduced mobility in the lumbar spine at the examination in 1967 was found more frequently in probands than in controls. The differences no doubt depended on the age but may also have been caused by a greater frequency of lumbago and sciatica among the probands in 1967. In the controls who had lumbar spine syndrome at the time of examination there was a significantly greater frequency of slightly reduced mobility in the cervical spine.

per cent Normal thoracic spine was noted in 71.7 per cent of the probands and 73.6 per cent of the controls. In the lumbar spine the corresponding figures were 73.6 per cent in the probands and 75 per cent in the controls. Slightly more normal thoracic spines were found in the controls who previously had not had symptoms in the lumbar spine as compared to those with earlier symptoms.

Scoliosis of the thoracic spine was noted in 9.4 per cent of the probands and 9.8 per cent of the controls, and of the lumbar spine in 8 per cent of the probands and 8.9 per cent of the controls. No differences were observed between those with earlier lumbar spine syndrome and those without previous symptoms. Nor were there any differences between those who at the examination were free of symptoms and those who had symptoms. Consequently, in this series changes of configuration cannot be regarded as the cause of spinal disorders of the type to which this investigation refers.

Painful palpation over spinal process

Table 9 in the Appendix shows the rate of painful palpation over the spinal process in different parts of the spine. Painful palpation refers to percussive tenderness with superficial or deep pain in one or several vertebrae and not in the musculature. This phenomenon was not often found. It was more common in the cervical spine, but rare in the spinal processes of the thoracic vertebrae. In the cervical and lumbar spine the symptom was observed statistically significant more often in the probands than in the controls ($\chi^2 = 11.4^{***}$ d.f. = 1) for lumbar spine, and ($\chi^2 = 9.63^{**}$ d.f. = 1) for cervical spine. The frequency was low and without significant differences in the thoracic spine. There was a greater number of probands with lumbar spine symptoms who had percussive tenderness in the cervical spine as compared to those who had no symptoms at the examination ($\chi^2 = 9.81^{**}$ d.f. = 1).

Besides differences between the probands and the controls who at the examination either were free of symptoms or else had symptoms, the controls with earlier symptoms had significantly more often tenderness in the lumbar spinal processes as compared to those without symptoms ($\chi^2 = 4.19^*$ d.f. = 1). A comparison between probands and controls without and with symptoms revealed ($\chi^2 = 15.74^{***}$ d.f. = 1) and ($\chi^2 = 9.21^{**}$ d.f. = 1) respectively.

Summary Painful palpation over the spinal process is significantly more common in probands than in controls. The same observation was made when subjects with earlier symptoms were compared with those without symptoms and with subjects who had existing lumbar spine disorders. Almost the same phenomenon was found with respect to the cervical spine in probands and controls who either had or had not lumbar spine disorders. It is plausible that the onset of cervical spine symptoms in subjects with lumbar spine symptoms could point to a non-differentiated spinal disease. The low frequency of subjects

higher in the probands Lasègues sign ($X^2 = 15.47^{***}$ d.f. = 2) and S.L.R. straining ($X^2 = 27.64^{***}$ d.f. = 2). No controls who were symptom free either previously or at the examination in 1967 had positive Lasègues sign or S.L.R. straining.

Neurological findings

Table 13 in the Appendix shows the most common neurological symptoms as found in the series. In 6 probands and in one control neurological disturbances could be connected with the low spinal disorders. Three probands and two controls had persisting neurological symptoms remaining from sciatica, previously treated with surgery and 17 probands and 5 controls had sciatica remaining from earlier conservative treatment. Two probands and two controls had neurological symptoms due to other reasons (polio, MS). Various types of neurological disturbances occurred in a statistically significant greater frequency among the probands as compared to the controls ($X^2 = 11.53^*$ d.f. = 4). The former also had sciatica more often both before and at the examination in 1967. In the controls who previously had no symptoms only one case had neurological disturbances, one had a slight knee jerk on the left side. In those with earlier symptoms there were different types of neurological disturbances in a considerably greater amount according to Table 13 in the Appendix. Neurological disturbances were found in fewer of the cases who had no symptoms on examination in 1967 as compared to those who on the same occasion had symptoms. The difference, however, was not statistically significant.

Summary. Neurological disturbances are significantly more common in probands than in controls as well as in those with earlier symptoms as compared to controls without symptoms. The difference depends on more cases of sciatica in the probands both before and at the examination in 1967. The operative and conservative treatments of sciatica were compared. Past histories in which paresthesia and paresis had been stated were compared with neurological disturbances at the examination. There was no difference between those treated surgically and conservatively.

Neurological disturbances in the upper extremities

Lasègues' mechanism (straight leg raising test) and etiology in the lower extremities have been subject to discussion in the literature and are also well defined (Lasègue 1864, de Boerermann 1884, Schober 1940, Hohmann, Hackenbrock et Lindemann 1957, Turek 1959, Adams 1964). An endeavour has been made to find a similar phenomenon in the upper extremities, and has then been called a stretch test (Duhungschmerz, Hohmann, Hackenbrock et Lindemann 1957). However it is less well defined and is no doubt of less clinical value. Stretch test is regarded as positive if there is radiating pain in the shoulder region on abduction and backward movement of the arm.

Pain on mobility test of spine

Table 11 in the Appendix shows the reaction of pain in various parts of the spine both in extreme movements and in movements on the whole. Extreme movements included maximal active movement of the spine. In 86.8 per cent, the probands could move their cervical spine without pain and the same applied to the controls in 88.7 per cent. There was no difference in the control group with or without earlier lumbar spine syndrome. Pain on mobility test of the cervical spine was significantly more often found in the controls who at the time of examination in 1967 had lumbar spine symptoms as compared to those without symptoms ($X^2 = 6.62^{**}$ d.f. = 1).

The frequency of pain on mobility of the thoracic spine was very low, and there were no statistically significant differences between the probands and the controls or between the groups who before or at the examination in 1967, either had or had not lumbar spine syndrome.

Pain on mobility of the lumbar spine occurred in 25.9 per cent of the probands, and in 6.1 per cent of the controls. The difference was statistically significant ($X^2 = 24.12^{***}$ d.f. = 1), and was caused by the greater number of probands who at the examination in 1967 were included in the Diagnostic Groups 4, 6 and 7. At the examination in 1967, 19 probands (16.8%) had pain when testing the mobility of the spine and 34 (30.1%) in connection with extreme movements. Contrary to this, only one control (1.7%) had pain when testing the mobility of the spine and 5 (8.5%) with extreme movements.

The difference between the subjects who at the examination either had no symptoms or symptoms is natural for the probands ($X^2 = 52.25^{***}$ d.f. = 1) and for the controls ($X^2 = 9.21^{**}$ d.f. = 1).

Subjects with earlier lumbar spine disorders did not reveal any statistically significant greater frequency of pain on mobility as compared to those who had no symptoms.

Summary Pain on mobility of the spine occurred significantly more often in the probands and the controls who had lumbar spine disorders at the time of examination in 1967 than those who had no symptoms and also more often in probands than controls. This depended on the higher frequency of existing lumbago and sciatica in the probands at the examination in 1967.

Lasègue's sign (Straight Leg Raising Test)

Positive Lasègue's sign was found according to Table 12 in the Appendix in a total of 15 probands and one control. In 7 of the probands Lasègue's sign was positive bilaterally and the same applied to the singular control.

Positive Lasègue's sign is included in the definition of the Diagnostic Groups 4, 6 and 7. Due to an increased number of cases of lumbago and sciatica in the group of probands, Lasègue's sign and SLR straining were also significantly

14 Roentgen Examination

After excluding seven pregnant females six males and four females who refused to be roentgenologically examined and who were excluded at the matching 195 probands and matched controls could be examined. Out of these 119 were 109 males and 10 females. This constitutes 92 per cent of the 212 subjects who were clinically examined.

TABLE 15 Various Ages of Subjects Examined

Age	Males	Females
20—29	10 (—1)	7 (—5)
30—39	15	5 (—3)
40—49	29 (—2)	24 (—2)
50—59	41 (—2)	26 (—1)
60—69	24 (—1)	13
70—		1
Total	119 (—6)	76 (—11)

MEAN AGE

Males 49.54 ± 1.09 years

Females 49.67 ± 1.33 years

Despite the non response of six males and eleven females there was no difference in age between the entire clinical and the roentgenologically examined subjects. In this series roentgen examination was performed of the thoracic and the lumbar spine using the routine technique of Roentgen Diagnostic Department I, Sahlgrenska sjukhuset Gothenburg. The examination was carried out with the patient in a recumbent position with one AP and one lateral projection of the thoracic spine. The same projections were used for the lumbar spine with an additional AP and lateral projection for the lumbosacral and sacroiliac joint. Roentgen of the cervical spine was excluded as the extra work included in obtaining an advantageous result would have been too time-consuming for the Department. In order to obtain a further analysis the controls were classified in groups with those who had had earlier lumbar spine disorders (132 examined subjects mean age 51.19 ± 1.67 years) and those without previous symptoms (63 roentgenologically examined subjects mean age 48.76 ± 0.96 years). Those with symptoms were slightly older but not statistically significant. The probands were also divided into two groups and matched with the above mentioned control groups. Furthermore, the subjects were classified with respect to lumbar spine disorders at the time of examination.

Disc degeneration and spondylosis were defined roentgenologically in the following way:

The "stretch test" was positive in 15 probands and 10 controls at the examination. Reduced reflexions in the upper extremities were noted in two controls. One control had reduced sensibility. For further details see separate table No 15.

Orthopaedic changes in lower extremities

Lowered Pelvis more than 1—2 cm, was found in 12 probands and 9 controls. There was no difference between those without and with symptoms.

Reduced mobility in the right hip joint occurred in three probands and six controls, in the left hip joint in five probands and seven controls. Reduced mobility in the knee and foot joints occurred in 12 probands and 9 controls. Deformities of feet and toes were observed in 24 probands and 59 controls. Other deformities could be noted in the lower extremities in 13 probands and 22 controls.

There were no statistically significant differences in the shape of the extremities and the pelvis when comparing between probands and controls with or without symptoms at the examination in 1967. Nor were there any deviations between the controls who had or who had not had previous lumbar spine syndrome. For further details see separate table.

Summary of objective findings on examination in 1967

The clinical examination of probands and controls resulted as follows:

Configurative changes in the spine did not reveal earlier or existing spinal disorders. Painful palpation over the spinal process occurred more often in probands than in controls both with earlier and existing symptoms at the time of examination in 1967, as compared to those without symptoms. The method, however, cannot be regarded as objectively reliable due to the subjectivity which is involved both from the point of view of the physician and the subject. The function of the spine and the pain reaction in connection with mobility caused significant differences only between the probands and the controls who on examination had symptoms and no symptoms respectively. More cases of positive Lasègue's sign depended on more cases of sciatica among the probands. This also applied to neurological disturbances in the lower extremities. The occurrence of neurological disturbances afforded satisfactory information as to the presence of earlier sciatica both in operated and non operated cases. There was no correlation between a lowered pelvis of more than 1—2 cm and changes in the lower extremities and lumbar spine disorders. Neurological disturbances in the upper extremities rarely occurred according to the experience as mentioned in the literature (Hult 1954 a b, Adams 1964, Hirsch 1966).

Satisfactory information as to the subject's existing spinal disorders will be obtained on objective examination. If there are no neurological disturbances present it is impossible to state definitely earlier occurrence of lumbar spine disorders.

14 Roentgen Examination

After excluding seven pregnant females six males and four females who refused to be roentgenologically examined and who were excluded at the matching 195 probands and matched controls could be examined. Out of these 119 were males and 76 females. This constitutes 92 per cent of the 212 subjects who were clinically examined.

Age	Males	Females
20—29	10 (—1)	7 (—5)
30—39	15	5 (—3)
40—49	29 (—2)	24 (—2)
50—59	41 (—2)	26 (—1)
60—69	24 (—1)	13
70—		1
Total	119 (—6)	76 (—11)

MEAN AGE

Males 49.54 \pm 1.09 years

Females 49.67 \pm 1.33 years

Despite the non response of six males and eleven females there was no difference in age between the entire clinical and the roentgenologically examined subjects. In this series roentgen examination was performed of the thoracic and the lumbar spine using the routine technique of Roentgen Diagnostic Department I, Sahlgrenska sjukhuset, Gosterburg. The examination was carried out with the patient in a recumbent position with one AP and one lateral projection of the thoracic spine. The same projections were used for the lumbar spine with an additional AP and lateral projection for the lumbo-sacral and sacroiliac joint. Roentgen of the cervical spine was excluded as the extra work included in obtaining an advantageous result would have been too time consuming for the Department. In order to obtain a further analysis the controls were classified in groups with those who had had earlier lumbar spine disorders (132 examined subjects mean age 51.19 \pm 1.67 years) and those without previous symptoms (63 roentgenologically examined subjects mean age 48.76 \pm 0.96 years). Those with symptoms were slightly older but not statistically significant. The probands were also divided into two groups and matched with the above mentioned control groups. Furthermore the subjects were classified with respect to lumbar spine disorders at the time of examination.

Disc degeneration and spondylosis were defined roentgenologically in the following way

The stretch test" was positive in 15 probands and 10 controls at the examination. Reduced reflexions in the upper extremities were noted in two controls. One control had reduced sensibility. For further details see separate table No 15.

Orthopaedic changes in lower extremities

Lowered Pelvis more than 1—2 cm was found in 12 probands and 9 controls. There was no difference between those without and with symptoms.

Reduced mobility in the right hip joint occurred in three probands and six controls; in the left hip joint in five probands and seven controls. Reduced mobility in the knee and foot joints occurred in 12 probands and 9 controls. Deformities of feet and toes were observed in 24 probands and 59 controls; other deformities could be noted in the lower extremities in 13 probands and 22 controls.

There were no statistically significant differences in the shape of the extremities and the pelvis when comparing between probands and controls with or without symptoms at the examination in 1967. Nor were there any deviations between the controls who had or who had not had previous lumbar spine syndrome. For further details see separate table.

Summary of objective findings on examination in 1967

The clinical examination of probands and controls resulted as follows:

Configurative changes in the spine did not reveal earlier or existing spinal disorders. Painful palpation over the spinal process occurred more often in probands than in controls both with earlier and existing symptoms at the time of examination in 1967, as compared to those without symptoms. The method, however, cannot be regarded as objectively reliable due to the subjectivity which is involved both from the point of view of the physician and the subject. The function of the spine and the pain reaction in connection with mobility caused significant differences only between the probands and the controls who on examination had symptoms and no symptoms respectively. More cases of positive Lasègue's sign depended on more cases of sciatica among the probands. This also applied to neurological disturbances in the lower extremities. The occurrence of neurological disturbances afforded satisfactory information as to the presence of earlier sciatica both in operated and non-operated cases. There was no correlation between a lowered pelvis of more than 1—2 cm and changes in the lower extremities and lumbar spine disorders. Neurological disturbances in the upper extremities rarely occurred according to the experience as mentioned in the literature (Hult 1954 a, b; Adams 1964; Hirsch 1966).

Satisfactory information as to the subject's existing spinal disorders will be obtained on objective examination. If there are no neurological disturbances present, it is impossible to state definitely earlier occurrence of lumbar spine disorders.

FIG 5
Roentgenological Changes in the Various Groups Showing Distribution According to Mean Age

1- Diffuse roentgenological changes in both thoracic and lumbar spine

2- Roentgenological changes limited to lumbar spine

3- Roentgenological changes limited to thoracic spine

4- Without roentgenological changes

Disc degeneration included each reduction of the intervertebral distance as compared to the adjoining intervertebral space. As regarded the lumbo sacral disc, normally revealing variations degenerative changes were also required of the surrounding edges of the vertebral body.

Spondylosis included each type of bone projecting from the edge of the vertebral body (exostosis). As routine projections do not allow a sure diagnosis of intervertebral joint arthritis no attention was paid to this (Blom 1967, and Scheller 1967).

The roentgen series were studied to find out the occurrence and localization of the above specified pathological changes in each segment of the thoracic and lumbar spine, configurative changes deviations from the shape of the intervertebral space, e.g. Scheuermann's disease, Schmorl's noduli, osteoporosis, Bechterew's disease, congenital changes, spondylosis and spondylolisthesis, spina bifida, block vertebrae and transitional vertebrae. Furthermore a specification was made of scoliosis, degenerations of a disc and spondylosis.

In this investigation were included the roentgenological findings which occurred in a number of subjects who were suitable for statistical analysis.

Roentgenological changes (Tables 14 Appendix)

Roentgenological changes of some kind occurred in 96.9 per cent of the probands and in 90.3 per cent of the controls. The changes were localized either in the thoracic or the lumbar spine or both in the thoracic and the lumbar spine. There was a statistically significant greater frequency of probands than controls who had roentgenological changes ($\chi^2 = 4.44$, d.f. = 1).

The difference between the controls who had earlier lumbar spine syndrome and those without previous symptoms is not significant. There were no differences between those without or with symptoms at the examination in 1967.

The above mentioned statistically significant differences are found in the group with changes both in the thoracic and the lumbar spine. 64.1 per cent of controls and 76.5 per cent of probands.

The age and sex distribution showed that the examined subjects who had no roentgenological changes either among the probands or the controls were significantly younger than those with roentgenological changes ($p(t) < 0.05$). The group with changes only in the thoracic or lumbar spine was significantly younger than those with roentgenological changes in both the thoracic and the lumbar spine ($p(t) < 0.05$). In the ages exceeding 50 years the disc degeneration and changes of spondylosis became more severe and more extended.

Roentgenological changes

The roentgenological changes depend on the age. In young individuals degenerative disturbances are rarely found but with increasing age they are localized either in the thoracic or the lumbar spine and at the age of 50 years they have a tendency to involve both the thoracic and the lumbar spine.

FIG. 5.
Roentgenological Changes in the Various Groups Showing Distribution According to Mean Age

- 1= Diffuse roentgenological changes in both thoracic and lumbar spine
- 2= Roentgenological changes limited to lumbar spine
- 3= Roentgenological changes limited to thoracic spine
- 4= Without roentgenological changes

Localization of roentgenological changes

A roentgentopographic classification of spinal changes in seven possible combinations according to Table 15 in the Appendix was statistically analysed with consideration taken to all the groups. There were no significant differences in any localization between the probands and the controls. Nor were there any deviations between controls who had not experienced earlier spinal symptoms and those who had symptoms and matched probands or between those without or with symptoms at the examination.

Scoliosis (Table 16, Appendix)

With the roentgen technique used, the existing changes of the configuration depended on the position of the subject on exposure. When describing scoliosis the roentgenologist defined it as a spinal curvature in the frontal plane with or without rotation. The designations used were plausible, slight, moderate. There were three cases of severe scoliosis in the series: one proband and two controls. All of them had had earlier spinal disorders and stated that they suffered from lumbar spine syndrome also at the time of examination in 1967. This small number does not permit any statistical analysis.

Congenital vertebral changes

In the roentgen series there were three types of congenital changes of the vertebrae: spina bifida occulta, transitional vertebrae and spondylolysis with or without spondylolisthesis.

1 Spina bifida occulta (Table 17 Appendix)

Spina bifida occulta only occurred in the lumbar spine and in the sacrum of 7.7 per cent of the probands and in 10.8 per cent of the controls. There were no statistically significant changes when comparing between the various groups.

2 Transitional vertebrae (Table 18 Appendix)

In the probands there were 14.8 per cent who had transitional vertebrae. Out of these 44.8 per cent were symmetrical, 55.2 per cent asymmetrical. Out of the probands 46.1 per cent with symmetrical and 56.2 per cent with asymmetrical transitional vertebrae had no symptoms at the examination in 1967. In the controls there were transitional vertebrae in 18 per cent symmetrical, in 47 per cent asymmetrical, in 52.9 per cent. Out of those with symmetrical transitional vertebrae 68.8 per cent of the controls had no symptoms at the examination and the corresponding figure for the asymmetrical subjects was 77.8 per cent. A slightly larger number of earlier symptom free individuals had asymmetrical transitional vertebrae. The difference, however, was not statistically significant.

3 Spondylolysis with or without spondylolisthesis (Table 19 Appendix)

When studying the series it was found that among the controls who previously had never had symptoms from the lumbar spine there was not one single case of spondylolysis or spondylolisthesis. The difference between the above mentioned group and the controls with spondylolysis and spondylolisthesis respectively who had previously had lumbar spine disorders was statistically significant ($\chi^2=4.77^*$ $df=1$). Spondylolysis and spondylolisthesis occurred more often in the controls with earlier symptoms than in those without earlier lumbar spine disorders. In the spondylolysis and spondylolisthesis series there were more subjects who had not been sick listed for spinal disorders in comparison with the probands. This means that spondylolysis and spondylolisthesis may not seldom cause spinal disorders however to such a slight degree that the subject as a rule does not report himself sick.

Schmorl's noduli (Table 20 Appendix)

Schmorl's noduli in the thoracic and lumbar spine occurred in 12.8 per cent of the probands and in 6.1 per cent of the controls. In the controls without earlier lumbar spine disorders the frequency was 9.5 per cent and in those with earlier symptoms 4.5 per cent. There were no differences between those who were symptom free and those with symptoms at the examination in 1967. Schmorl's noduli therefore cannot be regarded as significant for the earlier or existing spinal disorders of the subjects.

Osteoporosis (Table 21 Appendix)

There were no statistically significant differences when studying the roentgen series. However it must be pointed out that the reliability of the roentgen technique in osteoporosis is dubious. Out of the two subjects who had severe osteoporosis and pathological fractures there was one proband who at the examination had lumbar spine insufficiency. The other was a control who had never had any symptoms.

Disc degeneration (Table 22 Appendix)

Various degrees of disc degeneration occurred in 46.2 per cent of the probands and in 31.8 per cent of the controls. The number of probands is statistically significantly higher than the number of controls ($\chi^2=8.45^{**}$ $df=1$).

Disc degeneration in controls with lumbar spine disorders was found in 37.2 per cent and in those without earlier lumbar spine disorders in 18.9 per cent ($\chi^2=6.97^*$ $df=1$). A significantly greater number of sick listed and also non sick listed subjects with lumbar spine disorders had disc degeneration as compared to the controls without earlier lumbar spine syndrome. In order to analyse these differences in detail disc degeneration was classified in age and sex (Table 23 Appendix). There were no statistically significant differences

between males and females. The mean age in both probands and controls with degenerative changes of a disc was statistically significant higher than the mean age of subjects without changes. The difference is about 9 years (Table 23, Appendix). Furthermore, in both the control groups those who had degeneration of a disc were of a significantly higher age. The difference in age between those who had not had spinal disorders earlier was 7 years, and between those with earlier spinal disorders it was 14 years (Table 23, Appendix).

The occurrence of roentgenologically verified disc degeneration in various age groups is illustrated in Fig. 6.

The diagram shows how disc degeneration increases with age, advancing in all groups. The lowest difference in frequency was found between the probands and the controls with symptoms. The highest difference in frequency was observed between the probands and the previously healthy controls. When various age groups were statistically analysed, it was noted that the above mentioned significant difference between the probands and the controls was only found in the group with moderate disc degeneration on one level, and only in the age group 50—59 years ($X^2=4.74$, $d.f.=1$) (Table 23, Appendix).

There were also differences in ages exceeding 60 years but they were not statistically significant. The difference between the control groups in various types of disc degeneration was significant only above the age of 40 years. There were also severe types of disc degeneration which depended on the age. An interruption of the increasing frequency with advancing ages may be due to the low number of examined subjects included in certain age groups.

Summary Frequency and degree of disc degeneration increases with advancing age. In those with symptoms, the increase begins earlier and the curve is higher but statistically significant differences occur only in ages exceeding 40 years. The author cannot support *Seterin's* (1943) conception. In the series there was a pronounced parallelism between the age and the degree of disc degeneration. Roentgenologically verified disc degeneration did not reveal existing symptoms in the subject. It is plausible that subjects with disc degeneration previously had spinal disorders to a greater extent than those without disc degeneration. Or the reverse: patients with spinal disorders stood a greater chance than healthy subjects to exhibit these kinds of roentgenological changes with increasing age.

Spondylosis (Table 24, Appendix)

Spondylosis in various degrees was found in a large number of the examined subjects: in 84.1 per cent among the probands and in 72.8 per cent among the controls. The difference is statistically significant ($X^2=7.34^{**}$ d.f.=1). Severe spondylosis was more common in the probands and contributed to a decided statistically significant difference on one or more levels ($X^2=8.82^{**}$ d.f.=1). There were no significant differences between the control groups nor the sex distribution nor the classification of diagnoses at the time of examination in 1967. As in disc degenerations the occurrence of spondylosis in various age- and examination groups was followed up.

Similar to disc degeneration it was found that the subjects who had no spondylosis were statistically significantly younger than those with spondylosis. The number of subjects with spondylosis increased with their age, however mostly in those who had been sick listed previously for lumbar spine disorders, slightly less in the non sick listed but with symptoms and least in those without earlier symptoms. The frequency of earlier symptom free controls deviated to a certain extent and was caused by the low number of patients who had been selected at random.

There is a significant difference between the probands and the controls. When the series is classified in age groups the significant differences are eliminated, probably depending on the groups becoming too small (Table 25, Appendix). The degree of spondylosis shows a parallelism with age. Too few patients result in a slight random deviation in severe degrees of spondylosis on one level.

Summary The phenomenae in spondylosis resemble those of disc degeneration.

FIG 7
% Roentgenological Evidence of Spondylosis in the Various Age Groups

parallelism with age both in quality and quantity. The number of cases of spondylosis is however greater in earlier sick listed subjects slightly less in non sick listed, but with symptoms and least in the controls with a previously healthy spine.

Summary of roentgenological findings

Roentgenological diagnosis as an indicator of a clinical spinal disease was only applicable to the ages exceeding 40 years for various types of disc degeneration and severe degrees of spondylosis. Within the other age groups there was no parallelism. It must be pointed out however that moderate disc degeneration on one level may be interpreted differently especially on the L V—S I level.

Roentgenologically verified disc degeneration and spondylosis localized to the lumbar or the thoracic spine only become more severe and more extended in ages exceeding 50 years. Consequently roentgen examination cannot even in older groups disclose for certain the existing type of disease but may suggest the occurrence of earlier attacks which possibly resulted in sick listing.

The frequency of spondylolisthesis and spondylolysis was significantly higher among the controls with previous spinal disease as compared to those who had not had any symptoms and also in comparison with the earlier sick listed probands. Symmetrical and asymmetrical transitional vertebrae in previously symptom free subjects were more common than in those with symptoms. Therefore transitional vertebrae cannot be regarded as the cause of earlier or existing lumbar spine disorders.

15 Discussions and Conclusions

On the basis of the data resulting from this series the problems referred to in the introduction can be answered as follows:

1. The past history showed that lumbar spine syndrome had occurred in all the probands except one (who denied any disorders due to lapse of memory) and in 66.5 per cent of the controls (66.4 per cent males and 66.7 per cent females). *Hult* (1924 a, b) found incidence of low back pain in 78 per cent industry workers, 82 per cent woodsmen, 52.7 per cent males with light work and in 64.4 per cent males with heavy labour. *Hirsch* (1965, 1966) found that approximately 65 per cent of the Swedish people some time get lumbar spine disorders.

Lumbar spine disorders in young gainfully employed females occurred according to *Hirsch, Jonsson et Lewin* (1968) in a lower frequency (49%). The selection was representative for the female population of this country.

The incidence of low back pain in the present control series is in accordance with that stated by most authors. No difference in sex was noted. It should be pointed out that the controls are not representative of any statistically significant

uniform group of the population. The controls were selected only for the purpose of being matched with the probands. Using the National Health Service Records, it was possible to exclude from the intended controls, those who had been sick listed during the period 1955—1966 for lumbar spine disorders.

Among those with symptoms, lumbago occurred in 53.5 per cent of the probands and 46.1 per cent of the controls. Lumbar spine insufficiency was least common among the probands (18 %) and sciatica had the lowest frequency among the controls (22 %). Sciatica occurred among the probands in 28.5 per cent, spinal insufficiency among the controls in 31.9 per cent.

There was only a statistically significant difference in the group with lumbar spine insufficiency which had more controls than probands ($\chi^2=**$). Differences between sex only occurred among the controls, where there were more females than males who had sciatica ($\chi^2=*$) and more males than females had lumbago ($\chi^2=***$).

Lumbar spine disorders begin early in probands and controls before the age of 20 in 13.6 per cent and 7.1 per cent respectively. The number of probands increases between the ages 30—39 years (26.5 %) and of the controls the highest frequencies are reached at the ages between 20—29 years (33.3 %). In the older groups the number decreases both in probands and controls and in the group ranging from 60—69 years only 5 probands (2.4 %) and 4 controls (2.8 %) had their first attack. The mean age of probands and controls males and females was close to 35 years and there was no statistically significant difference. These findings are very close to those of Friberg et Hirsch (1949), Unander-Scharin (1950), Hult (1954 a) and Hirsch (1955).

Lumbar spine insufficiency was mostly present among the youngest subjects and predominated in the age group prior to 29 years and then the frequency decreased. A certain increase was observed in the group ranging from 40—49 years in the controls and from 50—59 years in the probands.

Lumbago increased with only a few interruptions to the highest agegroups among the probands and to the age group from 50—59 years among the controls.

Sciatica only a small percentage occurred among the younger age groups up to between 20—29 years increased among the probands to 35 per cent in the group between 50—59 years and to 39 per cent among the controls in the ages from 40—49 years. These results are well in accordance with those observed by Hult (1954 a, b) and Hirsch, Jonsson et Leam (1968).

The frequency of lumbar spine disorders often of the insufficiency type but also lumbago and sciatica occurring at ages under 20 years is higher than that found by Unander-Scharin (1950) but corresponds to the investigations carried out by the above mentioned authors as well as to the patho-anatomical observations of disc degeneration reported by Hirsch et Schajowicz (1952) and Hirsch, Schajowicz et Galante (1967).

2 In studying the development of the three most common types of lumbar spine syndrome the series revealed that 42.5 per cent of the probands and 76.6 per cent of the controls only had one and the same type of lumbar spine disorders or only one homogeneous attack of disease so-called consistent cases. The frequency of consistent cases among the controls was significantly higher than in the probands and also significantly higher in males than females in both series. Variations of different types of lumbar spine disorders occurred in 57.5 per cent of the probands and in 23.4 per cent of the controls with symptoms. Contrary to the consistent type variations appeared in a statistically significant greater frequency in probands and females. Subjects with consistent symptoms were significantly younger than those with variations. The most common types of variation were lumbago and sciatica with lumbar spine insufficiency. Variations of lumbago with sciatica and sciatica with lumbago or variations with all the three most common types of lumbar spine disorders were rarely found. There was a statistically significant predomination among the probands with variations.

Provided that the probands were sick listed due to spinal disorders and generally revealed variations with various types of symptoms it could be assumed that the subjective sensation of the disease was more pronounced than in consistent types in which the controls predominated. This opinion is also supported by the fact that among the controls with consistent types of low back pain 43.5 per cent had one single attack of symptoms. Consistent cases of lumbar spine insufficiency with the controls predominating was according to these observations no exception from the rule. The occurrence of various types of lumbar spine disorders showed that the probands more often than the controls had experienced their symptoms as painful and difficult to endure often appearing in variations. On the other hand the controls as a rule had lumbar spine insufficiency and the consistent type. This is probably one of the explanations as to why the probands consulted a physician and were sick listed as a result.

3 Recurring lumbar spine disorders occurred in 90 per cent of the probands and in 66.7 per cent of the controls with symptoms ($X^2 = ***$). Recurrence or persisting lumbar spine disorders were also significantly more common among the probands than the controls not infrequently as variations with lumbar spine insufficiency among the probands. Recurrence of the initial symptoms occurred earlier and to a greater extent among the probands as compared to the controls. At the age of 40 years, nearly all the probands had had a recurrence while among the controls a further 20 years elapsed. With increasing age the plausibility of recurrence of lumbar spine disorders augments. However the number of recurrences does not only depend on the age. Subjects with more than eight recurrences or with persistent symptoms constituted a group in which the age was not higher than in that with a lower frequency of recurrences.

As the first attack of lumbar spine disorders the lumbar spine symptoms lasted for a shorter time as compared to most of the recurrences. This applied both

uniform group of the population. The controls were selected only for the purpose of being matched with the probands. Using the National Health Service Records it was possible to exclude from the intended controls those who had been sick listed during the period 1955—1966 for lumbar spine disorders.

Among those with symptoms, lumbago occurred in 53.5 per cent of the probands and 46.1 per cent of the controls. Lumbar spine insufficiency was least common among the probands (18%) and sciatica had the lowest frequency among the controls (22%). Sciatica occurred among the probands in 28.5 per cent, spinal insufficiency among the controls in 31.9 per cent.

There was only a statistically significant difference in the group with lumbar spine insufficiency which had more controls than probands ($\chi^2=**$). Differences between sex only occurred among the controls where there were more females than males who had sciatica ($\chi^2=*$) and more males than females had lumbago ($\chi^2=***$).

Lumbar spine disorders begin early in probands and controls before the age of 20 in 13.6 per cent and 7.1 per cent respectively. The number of probands increases between the ages 30—39 years (26.5%) and of the controls, the highest frequencies are reached at the ages between 20—29 years (33.3%). In the older groups the number decreases both in probands and controls and in the group ranging from 60—69 years only 5 probands (2.4%) and 4 controls (2.8%) had their first attack. The mean age of probands and controls, males and females, was close to 35 years and there was no statistically significant difference. These findings are very close to those of *Friberg et Hirsch* (1949), *Unander-Scharin* (1950), *Hult* (1954 a) and *Hirsch* (1955).

Lumbar spine insufficiency was mostly present among the youngest subjects and predominated in the age group prior to 29 years and then the frequency decreased. A certain increase was observed in the group ranging from 40—49 years in the controls and from 50—59 years in the probands.

Lumbago increased with only a few interruptions to the highest agegroups among the probands and to the age group from 50—59 years among the controls.

Sciatica only a small percentage occurred among the younger age groups up to between 20—29 years increased among the probands to 35 per cent in the group between 50—59 years and to 39 per cent among the controls in the ages from 40—49 years. These results are well in accordance with those observed by *Hult* (1954 a b) and *Hirsch Jonsson et Lewin* (1968).

The frequency of lumbar spine disorders, often of the insufficiency type but also lumbago and sciatica occurring at ages under 20 years is higher than that found by *Unander-Scharin* (1950) but corresponds to the investigations carried out by the above mentioned authors as well as to the patho-anatomical observations of disc degeneration reported by *Hirsch et Schajowicz* (1952) and *Hirsch Schajowicz et Galante* (1967).

within the cervical and lumbar spine. This phenomenon was more often found among those with earlier symptoms as compared to those without symptoms. The difference was also pronounced when in 1967 subjects with symptoms were put into relation with those who had no symptoms.

There were statistically significant differences between the probands and the controls with regard to the function of the spine. Significantly more probands than controls deviated one way or the other from the normal pattern of mobility in both the cervical and the lumbar spine ($\chi^2 = ***$) or experienced pain at the examination in the cervical and lumbar spine ($\chi^2 = ***$). The differences depended on the larger number of probands than controls having symptoms at the examination. The mobility test did not result in any retrospective data on spinal disease.

Lasegue's sign was positive in a significantly greater number of probands than controls ($\chi^2 = ***$). Furthermore there were neurological disturbances significantly more often among the probands than the controls ($\chi^2 = *$). The significant deviation was caused by a higher number of probands than controls with existing lumbago-sciatica at the examination in 1967. Neurological disturbances revealed no significant information as to earlier existing sciatica.

No significant deviations between the probands and the controls were found when studying the pelvis and the lower extremities and could not be correlated to earlier or existing low pain (Hult 1954 b).

In summarizing there were significantly more often objective findings in each proband than in each control, the diagnosis being acute lumbago and sciatica ($\chi^2 = ***$). Also in the Diagnostic Group 3, either with completely negative or insignificant clinical findings, where however subjective symptoms of tiredness, weakness, stiffness or dull pain in the lumbar spine (lumbar spine insufficiency) was noted, the probands predominated significantly as compared to the controls ($\chi^2 = *$). The clinical objective findings on examination selected at random corresponded to the existing subjective symptoms of the individual. In those who at the examination had symptoms of lumbago or sciatica, the objective findings corresponded well. In lumbar spine insufficiency there were rarely objective changes in the lumbar spine and the diagnosis was made on the basis of the subject's own description of his symptoms.

6. The investigation in 1967 revealed that subjects with lumbar spine syndrome had a significantly greater frequency of restricted mobility than those without symptoms. This also applied to the cervical spine and pain experienced at the mobility test of the cervical spine. It has been pointed out that the spine is a functional unit and that the cervical and thoracic spine symptoms among subjects with lumbar spine symptoms are pronounced (Hult 1954). In the present investigation more than half of the probands and more than 1/3 of the controls had experienced symptoms earlier in the cervical spine. Cervical spine symptoms occurred significantly more often among the probands than the

to the probands and the controls. A statistically significant higher number of controls had a shorter period of lumbar spine disorders than the probands. The probands experienced the recurrences more often and earlier than the controls. Their disease lasted longer and was often permanent. The recurrences give one explanation of the probands tending to report themselves as sick.

4 Subjective sensation of pain depends on many various factors and is difficult to assess objectively. From the onset until the examination in 1967 the probands on various occasions experienced a statistically significant greater intensity of pain than the controls ($\chi^2 = **$). Significantly more probands than controls felt pain in their lumbar spine day and night ($\chi^2 = ***$). No significantly greater number of controls had lumbar spine symptoms when standing for long periods or when sitting as correlated to a greater frequency of lumbar spine insufficiency among the controls. Ischialgia in all the examined cases of low back pain was more frequent among the probands than the controls. The deviation, however, was significant only when the probands were sick listed in 1964 ($\chi^2 = ***$).

All the probands consulted a physician due to low back pain, the controls in 51.1 per cent ($\chi^2 = ***$). Out of the controls who experienced intense pain/ache in the lumbar spine, 76.7 per cent had consulted a physician, which is a statistically significant lower number as compared to the probands ($\chi^2 = ***$).

Sensation of intense pain/ache in the spine may be caused by an intense nervous stimulant or a severe change in the spinal segment, i.e. a serious disease. Individual differences in sensation of pain/ache may be caused by various degrees of self control, different thresholds of pain and any psychosomatic combinations, psychogenous symptoms (Schanz 1921, Weiss et al. 1957, Rusk 1958, Bejerot 1966, White 1966, Walters 1966, Simmons 1966, Lindegard 1967, Flinchum 1967 and Knapp 1967).

When studying the history of pain on the above mentioned basis, a significant frequency of intense sensation of pain in the probands may correspond to a combination of various factors. Among the probands, painful lumbar spine disorders such as lumbago and sciatica predominated. They had recurrences more often and at an earlier stage than the controls, more often a variation of lumbar spine syndrome but rarely consistent types. The probands furthermore, as compared to the controls, had ischialgia frequently and not often merely localized pain. Again 23.3 per cent more probands than controls had consulted a physician because of intense sensation of lumbar spine symptoms, and in slight pain/ache the deviation was 9.4 per cent.

5 At the examination in 1967, no significant differences in the spinal configuration of the probands and the controls could be noted, nor were there any differences between those with earlier symptoms and those without symptoms.

Palpation over the spinal process revealed a significantly higher number of probands as compared to controls, who complained of deep percussive tenderness.

within the cervical and lumbar spine. This phenomenon was more often found among those with earlier symptoms as compared to those without symptoms. The difference was also pronounced when in 1967 subjects with symptoms were put into relation with those who had no symptoms.

There were statistically significant differences between the probands and the controls with regard to the function of the spine. Significantly more probands than controls deviated one way or the other from the normal pattern of mobility in both the cervical and the lumbar spine ($X^2 = ***$) or experienced pain at the examination in the cervical and lumbar spine ($X^2 = ***$). The differences depended on the larger number of probands than controls having symptoms at the examination. The mobility test did not result in any retrospective data on spinal disease.

Lasegue's sign was positive in a significantly greater number of probands than controls ($X^2 = ***$). Furthermore, there were neurological disturbances significantly more often among the probands than the controls ($X^2 = *$). The significant deviation was caused by a higher number of probands than controls with existing lumbago-sciatica at the examination in 1967. Neurological disturbances revealed no significant information as to earlier existing sciatica.

No significant deviations between the probands and the controls were found when studying the pelvis and the lower extremities and could not be correlated to earlier or existing low pain (Hult 1954: b).

In summarizing, there were significantly more often objective findings in each proband than in each control, the diagnosis being acute lumbago and sciatica ($X^2 = **$). Also in the Diagnostic Group 3, either with completely negative or insignificant clinical findings, where however subjective symptoms of tiredness, weakness, stiffness or dull pain in the lumbar spine (lumbar spine insufficiency) was noted, the probands predominated significantly as compared to the controls ($X^2 = *$). The clinical objective findings on examination, selected at random, corresponded to the existing subjective symptoms of the individual. In those, who at the examination had symptoms of lumbago or sciatica, the objective findings corresponded well. In lumbar spine insufficiency, there were rarely objective changes in the lumbar spine and the diagnosis was made on the basis of the subject's own description of his symptoms.

6. The investigation in 1967 revealed that subjects with lumbar spine syndrome had a significantly greater frequency of restricted mobility than those without symptoms. This also applied to the cervical spine and pain experienced at the mobility test of the cervical spine. It has been pointed out that the spine is a functional unit and that the cervical and thoracic spine symptoms among subjects with lumbar spine symptoms are pronounced (Hult 1954). In the present investigation, more than half of the probands and more than 1/3 of the controls had experienced symptoms earlier in the cervical spine. Cervical spine symptoms occurred significantly more often among the probands than the

controls ($X^2 = *$) There was no significant difference on the other hand in thoracic spinal symptoms (23.1% of probands and 17.9% of controls) Symptoms from both the cervical and the thoracic spine were present in 12.7 per cent of the probands and in 11.3 per cent of the controls There was no statistically significant deviation Recurrence of cervical spine symptoms among the probands rarely occurred as compared to lumbar spine symptoms (75.7%) Contrary to this, the controls more often had recurrences of the cervical spine symptoms than lumbar spine symptoms (75.6% of those with symptoms had recurrence in the cervical spine and 66.7% in the lumbar spine) Almost the same figures applied to the probands with recurrence of thoracic spine symptoms (73.5%) The controls had the same rate of recurrence of thoracic and lumbar spine symptoms (68.6%)

At the investigation in 1967 12.3 per cent of the probands and 7.5 per cent of the controls had cervical spine disorders Thoracic spine symptoms were found in 3.3 per cent of the probands and 2.4 per cent of the controls No statistically significant deviations were noted between the probands and the controls either with respect to recurrences or symptoms at the examination The onset of cervical spine disorders occurred a few years later than that of lumbar spine syndrome However, the occurrence of thoracic symptoms following lumbar spine syndrome was only insignificant Out of the probands who before the examination in 1967 had had cervical spine symptoms 69.1 per cent had had wry neck syndrome and 30.9 per cent brachialgia Among the controls the frequency of brachialgia was slightly lower (25.4%) The deviation is not significant Radiating pain in the arms and chest in cases who earlier had thoracic spine syndrome was uncommon only 9.7 per cent of the probands and 11.3 per cent of the controls with symptoms had experienced this

Similar to lumbar spine disorders the pain in the cervical and thoracic spine was experienced in various degree of intensity and duration all depending on the strain of the spine Consequently various types of cervical and thoracic spine syndrome were classified in wry neck and thoracic spine syndrome with/without radiating pain and in existing cervical and thoracic spine insufficiency There was no significant difference between the probands and the controls or between singular cervical and thoracic spine syndrome A combination of both cervical and thoracic spine syndrome however occurred significantly more often as cervical and thoracic spine insufficiency than wry neck and thoracic spine syndrome ($X^2 = ***$) This seems to point to the fact that the spine can be regarded as a functional unit and that there is a correlation between lumbar and cervical spine disorders and also although less obvious between lumbar and thoracic spine syndrome The onset and localization of symptoms in all spinal areas the history of pain and also the retrospective distribution of diagnoses were often in accordance

7 The roentgenological findings were expected to illustrate the differences

between probands sick listed earlier for lumbar spine disorders and their matched non sick listed controls. The attention was mainly directed towards congenital changes: disc degeneration and spondylosis. This was partly done as these diagnoses are most common in a clinical series partly because their importance and clinical relevance are mostly discussed.

The present study rarely included other types of roentgenological changes and did not permit statistical analysis. Technical errors in connection with the roentgen examination (changes in configuration osteoporosis) furthermore could complicate the analysis of the series.

There were three types of congenital changes in the vertebrae: spina bifida occulta, transitional vertebrae and spondylolysis with or without spondylolisthesis. Spina bifida occulta and transitional vertebrae did not differ significantly between the probands and the controls. It should be pointed out that a slightly larger number of earlier symptom free controls had asymmetrical transitional vertebrae as compared to symmetrical. The number of probands and controls with asymmetrical transitional vertebrae who had no symptoms at the examination in 1967 was identical with all the remaining probands and controls in the series. Spondylolysis with or without spondylolisthesis was found in the probands and the controls without any significant deviation. There was a statistically significant greater number of subjects with earlier symptoms who had these changes as compared to those without symptoms ($\chi^2 = *$).

Hibbs et Suzlt (1929), Hodges et Ieck (1937), Ingebrigtsen (1937), Brofeldt (1937), Willis (1941) and Huralt (1949) believed that congenital disturbance of the development and especially asymmetrical transitional vertebrae, spondylolysis and spondylolisthesis were of great pathological importance for lumbar spine disorders. Willis (1932), Friberg (1939), Hult (1954a, b), Hirsch (1965, 1966) on the contrary do not regard congenital changes of the vertebrae as pathognomonic for spinal disorders. A high frequency of congenital changes of the vertebrae, as reported both by Bistrom (1954) and Makowski (1963) in subjects with a healthy spine supports the conclusion made by the latter group of authors.

Different degrees of disc degeneration occurred statistically significant more often among probands than controls ($\chi^2 = *$) more often in subjects with earlier lumbar spine disorders than in those without symptoms ($\chi^2 = *$). The analysis and the age distribution however revealed that the difference between the probands and the controls depended on moderate disc degenerations on one level and merely in the age group ranging from 50—59 years ($\chi^2 = *$). The difference between those with early symptoms and those without symptoms was caused by various types of disc degeneration however only in those exceeding the age of 40 years. Patho-anatomical studies and clinical observations have repeatedly proved that disc degeneration depends on the age of the subject (Selmon 1929, Friberg 1941, Hirsch 1949, Hirsch et Schajowicz 1952, Hult

controls ($X = *$) There was no significant difference on the other hand, in thoracic spinal symptoms (23.1 % of probands and 17.9 % of controls) Symptoms from both the cervical and the thoracic spine were present in 12.7 per cent of the probands and in 11.3 per cent of the controls There was no statistically significant deviation Recurrence of cervical spine symptoms among the probands rarely occurred as compared to lumbar spine symptoms (75.7 %) Contrary to this the controls more often had recurrences of the cervical spine symptoms than lumbar spine symptoms (75.6 % of those with symptoms had recurrence in the cervical spine and 66.7 % in the lumbar spine) Almost the same figures applied to the probands with recurrence of thoracic spine symptoms (73.5 %) The controls had the same rate of recurrence of thoracic and lumbar spine symptoms (68.6 %)

At the investigation in 1967, 12.3 per cent of the probands and 7.5 per cent of the controls had cervical spine disorders Thoracic spine symptoms were found in 3.3 per cent of the probands and 2.4 per cent of the controls No statistically significant deviations were noted between the probands and the controls either with respect to recurrences or symptoms at the examination The onset of cervical spine disorders occurred a few years later than that of lumbar spine syndrome However, the occurrence of thoracic symptoms following lumbar spine syndrome was only insignificant Out of the probands who before the examination in 1967 had had cervical spine symptoms 69.1 per cent had had wry neck syndrome and 30.9 per cent brachialgia Among the controls the frequency of brachialgia was slightly lower (25.4 %) The deviation is not significant Radiating pain in the arms and chest in cases who earlier had thoracic spine syndrome was uncommon only 9.7 per cent of the probands and 11.3 per cent of the controls with symptoms had experienced this

Similar to lumbar spine disorders the pain in the cervical and thoracic spine was experienced in various degree of intensity and duration all depending on the strain of the spine Consequently various types of cervical and thoracic spine syndrome were classified in wry neck and thoracic spine syndrome with/without radiating pain and in existing cervical and thoracic spine insufficiency There was no significant difference between the probands and the controls or between singular cervical and thoracic spine syndrome A combination of both cervical and thoracic spine syndrome however occurred significantly more often as cervical and thoracic spine insufficiency than wry neck and thoracic spine syndrome ($X^2 = ***$) This seems to point to the fact that the spine can be regarded as a functional unit and that there is a correlation between lumbar and cervical spine disorders and also although less obvious between lumbar and thoracic spine syndrome The onset and localization of symptoms in all spinal areas the history of pain and also the retrospective distribution of diagnoses were often in accordance

7 The roentgenological findings were expected to illustrate the differences

subjects in both groups may have similar clinical findings irrespective of the group to which they belonged at the examination in 1967. Retrospective classification of lumbar spine disorders in various groups revealed spinal insufficiency significantly more often among the controls. It was also found that with increasing age nearly all the cases of lumbago and sciatica had variations with lumbar spine insufficiency, often of a persisting type. The predominance in probands with variations of this type was determined at the examination in 1967 in Group 3. They also had a higher mean age. Thus these probands seem to have been sick-listed due to a more severe type of spinal disease. Spinal insufficiency in subjects who had had earlier attacks of lumbago and sciatica seems to be of another type than the true insufficiency which begins in younger subjects and can be designated as chronic lumbago. The subjective sensation of pain/ache has been dealt with earlier in this chapter. It was found that among some of the probands the subjective sensation of pain was more intense than among the controls. Consistent types of lumbar spine insufficiency was found in 11.7 per cent of the probands and 7.6 per cent of these had insufficiency also in the cervical and thoracic spine. The corresponding figures for the controls were 3.8 per cent and 6.5 per cent respectively. Thus there are two groups who objectively reveal the same findings. The logic explanation of the probands being sick-listed seems to be that they experienced the subjective symptoms in a more intense degree.

3 Spinal disorders begin in comparatively young ages. With increasing age the risk of recurrences becomes greater. Up to about 45 years of age the recurrences are mostly of the same character as the initial attack (consistent cases). If the patient experiences severe pain both at the first onset and during the recurrences, he will often ask to be sick-listed. With increasing recurrences the period of sick-listing becomes longer (Table 16). *

In the higher ages (mean age 50.38 ± 0.86 years) the number of recurrences increased further and changed in character. Attacks of lumbago and sciatica became more uncommon and frequently variations would set in with lumbar spine insufficiency. The pain was less intense although often of the same character, the tendency to report sick became reduced.

All patients aged up to 70 years as a rule only have periods of lumbar spine insufficiency or permanent lumbar spine insufficiency irrespective of the initial type of lumbar spine disease. These disorders due to their changed character, justify the diagnosis chronic lumbago.

*) NOTE: Table 16 shows the mean figures of the sick-list periods and sick days of the proband during the years 1959—1966. Unfortunately there are certain errors. The mean figures are not stated per annum but for the entire period as the youngest age groups were not yet recruited as members of the National Health Service and the oldest were already pensioned. The table is merely used to illustrate the prognosis of the lumbar spine disorders. A detailed study of the sick-listing problem and socio-medical connections being compiled using this series as a basis (Westrin 1967—68).

1954 a b, and *Hirsch* 1965 1966) On the basis of the present investigation, the author cannot share *Severin's* (1943) opinion that the intensity of disc degeneration is independent of age In this series there was a pronounced parallelism between age and the degree of disc degeneration

Early disc degeneration cannot be illustrated on radiograms (*Goldthwait* 1911 *Knutsson* 1944 *Friberg et Hirsch* 1949, *Hirsch* 1951, *Morgan et King* 1957 *Leikkonen* 1959 *Abel et Harmon* 1960 *Wiltberger* 1963, *Lettin* 1967) As the lumbo-sacral disc normally presents large variations in height disc degeneration according to the earlier mentioned definition, was diagnosed at a later stage than discs on other levels

Spondylosis, another type of degenerative changes much resembled disc degeneration Spondylosis in various degrees depending on the age on one or several levels was significant in probands in relation to controls ($X^2 = **$) There were no differences between the control groups The data in the literature on the subject were very close to those found in this series *Bistrom* (1954) among 151 subjects with a symptom free spine found that spondylosis clearly depended on age *Hodges et Peck* (1937) in their paper mention a greater frequency of spondylarthritis among the controls as compared to the patients a fact which cannot be discussed in this connection as spondylarthritis of varying degrees is not included in the present roentgenological series Similar to *Hult* (1954 a b) the conclusion can be drawn that disc degeneration occurs significantly more often among those with earlier symptoms than among those with a healthy spine Furthermore congenital changes in the vertebrae excepting spondylolisthesis did not cause a higher frequency of low back pain and pretty frequently did spondylolisthesis cause moderate subjective symptoms

Lundberg (1959) concluded his paper with a question which the author considered of great importance and to which perhaps there is an answer Which are the factors in rather similar clinical findings that cause one individual to be incapacitated for work and the other to be a capable worker?

The results of the present investigation do not permit any settlement of the question with regard to one singular individual Further it is just as impossible to draw any conclusions in singular cases It is perhaps possible that this series can afford a few viewpoints as to how various population groups accept work

The clinical findings in 1967 on the whole differed significantly between the probands and the controls More probands than controls had reduced mobility and tenderness positive Lasque's sign and neurological disturbances In 15 probands and in one control only acute lumbago or sciatica was diagnosed at the examination Thus it is obvious that the probands i.e. those who due to spinal disorders had been incapacitated for work to a statistically significant higher degree than the controls — who carried on working despite spinal disease — had had a decidedly greater attack of spinal symptoms and thus an objectively verified reason to be sick listed On examination selected at random some of the

subjects in both groups may have similar clinical findings irrespective of the group to which they belonged at the examination in 1967. Retrospective classification of lumbar spine disorders in various groups revealed spinal insufficiency significantly more often among the controls. It was also found that with increasing age nearly all the cases of lumbago and sciatica had variations with lumbar spine insufficiency often of a persisting type. The predominance in probands with variations of this type was determined at the examination in 1967 in Group 3. They also had a higher mean age. Thus these probands seem to have been sick listed due to a more severe type of spinal disease. Spinal insufficiency in subjects who had had earlier attacks of lumbago and sciatica seems to be of another type than the true insufficiency which begins in younger subjects and can be designated as chronic lumbago. The subjective sensation of pain which he has been dealt with earlier in this chapter. It was found that among some of the probands the subjective sensation of pain was more intense than among the controls. Consistent types of lumbar spine insufficiency was found in 11.7 per cent of the probands and 76 per cent of these had insufficiency also in the cervical and thoracic spine. The corresponding figures for the controls were 31.8 per cent and 64.5 per cent respectively. Thus there are two groups who objectively reveal the same findings. The logical explanation of the probands being sick listed seems to be that they experienced their subjective symptoms in a more intense degree.

8 Spinal disorders begin in comparatively young ages. With increasing age the risk of recurrences becomes greater. Up to about 45 years of age the recurrences are mostly of the same character as the initial attack (consistent cases). If the patient experiences intense pain both at the first onset and during the recurrences he will often ask to be sick listed. With increasing recurrences the period of sick listing becomes longer (Table 16) *).

In the higher ages (mean age 55.38 ± 0.86 years) the number of recurrences increased further and changed in character. Attacks of lumbago and sciatica became more uncommon and frequently variations would set in with lumbar spine insufficiency. The pain was less intense although often of the same character. The tendency to report sick became reduced.

All patients aged up to 70 years as a rule only have periods of lumbar spine insufficiency or permanent lumbar spine insufficiency irrespective of the initial type of lumbar spine disease. These disorders due to their changed character justify the diagnosis chronic lumbago.

*) NOTE: Table 16 shows the mean figures of the sick list periods and sick days of the proband during the years 1955—1966. Unfortunately there are certain errors. The mean figures are not stated per annum but for the entire period as the youngest age groups were not yet included as members of the National Health Service and the oldest were already pensioned. The table is merely used to illustrate the prognosis of the lumbar spine disorder. A detailed study of the sick listing problem and socio-medical connections is being compiled using this series as a basis (West in 1967—68).

TABLE 16 Earlier Sick Listing of Probands

Age Years	Mean \pm SE of sick list period	Mean \pm SE of sick list days	Examined Subjects
20—24	1 53 \pm 0 19	76 80 \pm 34 57	15
25—29	1 75 \pm 0 49	118 13 \pm 87 15	8

65—	1 90 \pm 0 28	136 85 \pm 31 72	20
			Total 212

From the prognostic point of view the subjects should be noted who besides a consistent type of lumbar spine insufficiency or variation with lumbar spine insufficiency had insufficiency disorders also in the cervical or thoracic spine. In comparison with the others in this series they had a statistically significant greater frequency of recurrences, permanent lumbar spine disorders, a combination of disorders in all spinal parts, a greater number of sick days and sick listing periods without these differences having any reference to their age.

16 Summary

Among all the members of the Gothenburg Social Insurance Office who were sick listed for spinal disorders in 1964 approximately 9 000 members, a thirtieth part was selected, namely those who were born on the first day of any month. For this investigation there were thus 212 probands who were requested to come for examination. For earlier-mentioned reasons some failed to appear. Thus the total amounted to 76.5 per cent of the probands and 78.8 per cent of the controls. The same number of matched controls were selected for the same analysis. The matched controls were of the same age, sex and belong to the same sickness benefit category. Only Swedish born subjects were examined. The controls had not been reported sick by a physician during the period 1955—1966.

The author commenced this investigation by examining the general status of the probands and the controls. Then the past history was enquired into, including the symptoms in all the spinal parts from the onset until the investigation in 1967. The lumbar and thoracic spine of 195 probands and their matched controls were roentgenologically examined using the routine technique of the Roentgen Diagnostic Department I, Söhlgrenska sjukhuset, Gothenburg. Non response

(six males and eleven females) was caused by pregnancy, refusal to be roentgenologically examined and exclusion of matched pairs as the corresponding subject failed to appear. The examination was carried out so as to avoid subjective influence if possible. After the examination of the 424 individuals was completed, all the information was transferred to a code system and treated in a data processing machine. After tabulating the data various groups and classifications were statistically analysed and the probability calculations were expressed in chi square (χ^2) and t test with Degree of Freedom (d.f.)

The series thus consisted of 212 probands and the same number of controls out of whom 125 were males and 87 were females. The mean age of the males was 49.48 ± 1.07 years and of the females 47.71 ± 1.34 years. The age distribution of the probands who were a random sampling of subjects sick listed for lumbar spine disorders revealed that the morbidity of males and females increases to between 50—59 years and the lumbar spine symptoms then rapidly decline. The occurrence of lumbar spine disorders both before and at the examination in 1967 was statistically significant higher in the probands than in the controls.

The frequency of lumbar spine disorders was calculated in the control group at 66.5 per cent. If the symptoms in all the portions of the spine were included the figure was 81.2 per cent. There was no difference in sex and the mean age of those without earlier symptoms did not differ from that of those who had symptoms.

The age at the onset of the lumbar spine disorders as stated by the subjects gave the following values: mean age of male probands 35.36 ± 1.18 years, of female probands 34.77 ± 1.69 years, of male controls 34.88 ± 1.75 years and of female probands 34.12 ± 1.83 years.

Only one attack of lumbar spine disorders had occurred in 10 per cent of the probands and in 33.3 per cent of the controls with earlier symptoms. A statistically significant greater frequency of probands than controls reported recurrence of lumbar spine disorders. This also applied to more than eight attacks or permanent symptoms. The recurrences depended on the age of the controls and increased to between 40—49 years among the probands. The frequency of recurrences increased with age however not among those who had nine or more attacks of lumbar spine disorders. Most of the individuals with several recurrences or permanent lumbar spine disorders also had insufficiency in the lumbar region.

The first attack of lumbar spine disorders was shorter than most of the recurrences both in the probands and the controls. The controls had a shorter duration of lumbar spine disorders than the probands. The subjects were asked what in their opinion had caused the onset and the recurrences of the lumbar spine syndrome. 27.9 per cent of the probands and 23.4 per cent of the controls believed that accidents were the main cause. 27.4 per cent of the probands and 24.1 per cent of the controls mentioned heavy lifting. Infrequently trauma and

heavy lifting were stated as the cause of recurrences. The differences between the probands and the controls varied statistically significant and the selection could not serve as an explanation.

The subjective sensation of pain as experienced by the probands and the controls was using a slightly arbitrary assessment combined to one group, called intense pain/ache, and to another group called slight pain/ache. At each examination, significantly more probands than controls complained of intense pain/ache due to lumbar spine disorders. No differences in age influenced the pain sensation of the subjects. A statistically significant greater number of probands than controls experienced intense pain/ache both at the onset and in connection with most of the recurrences. Significantly more probands than controls of those who experienced intense pain/ache or slight pain/ache consulted a physician about their symptoms. Even if the history of pain does not serve as a guide when assessing the degree of lumbar spine syndrome it suggests however that the pain more often was experienced as intense by the probands than by the controls and that there was a general tendency to consult a physician.

Significantly more probands than controls had pain in the lumbar spine both day and night at all the periods of onset. Contrary to this more controls and probands only had symptoms during the day in connection with certain movements or strain. This points to the fact that acute and painful lumbar spine disorders more often occurred among the probands than the controls and that lumbar spine insufficiency had a higher frequency in the controls than in the probands.

At the onset 28.4 per cent of the probands and 21.9 per cent of the controls had ischialgia. The probands (45 %) who in 1964 were sick listed had ischialgia in a significantly higher frequency than the controls (19.8 %).

On the basis of the past history and the first symptoms, the series were classified in three groups of lumbar spine disorders: lumbar spine insufficiency, lumbago and sciatica. The groups were further divided into consistent cases and variations. As consistent cases were subjects who from the onset up to the examination in 1967 only had one type of low back pain or merely had a uniform attack of the disease. Variations included cases where the pattern of the disease changed, e.g. from sciatica to lumbar spine insufficiency or from lumbago to sciatica. Lumbar spine insufficiency and chronic lumbago could seldom be clearly differentiated. Consequently a differentiation between the two groups would have been very unreliable. Thus the diagnosis chronic lumbago includes lumbar spine insufficiency. Pain caused by coaching was not regarded as a spinal disease.

Among the described types of lumbar spine disorders lumbago was often found both in the probands and the controls. Lumbar spine insufficiency had a statistically significant greater frequency among the controls than the probands. Sciatica was rarely found in the controls.

There were only significant differences in sex among the controls. Significantly

more female controls than males had sciatica but lumbago occurred significantly more often in male than female controls

The age distribution of the subjects with the three most common lumbar spine disorders revealed that the youngest more often had lumbar spine insufficiency and lumbago. Already after the age of 20—29 years there was a decline in the probands and one decade later in the controls. The frequency of lumbago increased up to 50—59 years. Sciatica began with low frequencies in the younger subjects and increased in the probands up to 30—39 years and in the controls up to 40—49 years of age.

Consistent cases of the three most common lumbar spine disorders occurred more often among the controls than the probands both males and females. Rather often consistent cases were found in the group with lumbar spine insufficiency. Consistent cases among those with sciatica were most uncommon. The high frequency of lumbago in the series contributed to an increased number of subjects with consistent types of lumbago. The most common types of variation were lumbago and sciatica with lumbar spine insufficiency. This occurred more often in the probands than in the controls and even more often among females than males. The subjects with variations proved to be significantly older than those with consistent symptoms. Variations with lumbar spine insufficiency were rather unusual up to the age of 30—39 years after which the frequency increased. Variations with insufficiency caused most of the recurrences in both the probands and the controls. In this group there were 87 per cent of the subjects who complained only of persisting lumbar spine disorders.

Other variations than with lumbar spine insufficiency were uncommon in all the groups. The predominance of probands and the number of individuals in the series with age acted in the same way as those who had variation with lumbar spine insufficiency. In the higher ages nearly all the probands and controls with symptoms had lumbar spine insufficiency irrespective of which type of disease they had from the beginning.

A comparison between different types of lumbar spine disorders in 1967 revealed as a rule that those belonging to the lumbago group were free of symptoms and those belonging to the insufficiency group mostly had symptoms. Those with consistent types of lumbar spine disease mostly had no symptoms as compared to those with variations. Males had less symptoms than females.

The series was subjected to a study of symptoms from the cervical and thoracic spine. A significantly higher frequency of probands than controls had experienced cervical spine symptoms earlier (50.5% against 39.2%).

Thoracic spine symptoms occurred rarely in the past history (23.1% of probands and 17.9% of controls). 17.7 per cent of the probands and 11.3 per cent of the controls stated that they had suffered from cervical and thoracic symptoms earlier. The onset of cervical spine symptoms occurred about six years later than the lumbar spine disorders. The thoracic spine disorders mostly began at the

heavy lifting were stated as the cause of recurrences. The differences between the probands and the controls varied statistically significant and the selection could not serve as an explanation.

The subjective sensation of pain is experienced by the probands and the controls was, using a slightly arbitrary assessment combined to one group called intense pain/ache and to another group called slight pain/ache. At each examination significantly more probands than controls complained of intense pain/ache due to lumbar spine disorders. No differences in age influenced the pain sensation of the subjects. A statistically significant greater number of probands than controls experienced intense pain/ache both at the onset and in connection with most of the recurrences. Significantly more probands than controls of those who experienced intense pain/ache or slight pain/ache consulted a physician about their symptoms. Even if the history of pain does not serve as a guide when assessing the degree of lumbar spine syndrome it suggests however that the pain more often was experienced as intense by the probands than by the controls and that there was a general tendency to consult a physician.

Significantly more probands than controls had pain in the lumbar spine both day and night at all the periods of onset. Contrary to this more controls and probands only had symptoms during the day in connection with certain movements or strain. This points to the fact that acute and painful lumbar spine disorders more often occurred among the probands than the controls and that lumbar spine insufficiency had a higher frequency in the controls than in the probands.

At the onset 28.4 per cent of the probands and 21.9 per cent of the controls had ischialgia. The probands (45 %) who in 1964 were sick listed had ischialgia in a significantly higher frequency than the controls (19.8 %).

On the basis of the past history and the first symptoms the series were classified in three groups of lumbar spine disorders: lumbar spine insufficiency, lumbago and sciatica. The groups were further divided into consistent cases and variations. As consistent cases were subjects who from the onset up to the examination in 1967 only had one type of low back pain or merely had a uniform attack of the disease. Variations included cases where the pattern of the disease changed e.g. from sciatica to lumbar spine insufficiency or from lumbago to sciatica. Lumbar spine insufficiency and chronic lumbago could seldom be clearly differentiated. Consequently a differentiation between the two groups would have been very unreliable. Thus the diagnosis chronic lumbago includes lumbar spine insufficiency. Pain caused by coaching was not regarded as a spinal disease.

Among the described types of lumbar spine disorders lumbago was often found both in the probands and the controls. Lumbar spine insufficiency had a statistically significant greater frequency among the controls than the probands. Sciatica was rarely found in the controls.

There were only significant differences in sex among the controls. Significantly

more female controls than males had sciatica but lumbago occurred significantly more often in male than female controls

The age distribution of the subjects with the three most common lumbar spine disorders revealed that the youngest more often had lumbar spine insufficiency and lumbago. Already after the age of 20—29 years there was a decline in the probands and one decade later in the controls. The frequency of lumbago increased up to 30—39 years. Sciatica began with low frequencies in the younger subjects and increased in the probands up to 30—39 years and in the controls up to 40—49 years of age.

Consistent cases of the three most common lumbar spine disorders occurred more often among the controls than the probands both males and females. Rather often consistent cases were found in the group with lumbar spine insufficiency. Consistent cases among those with sciatica were most uncommon. The high frequency of lumbago in the series contributed to an increased number of subjects with consistent types of lumbago. The most common types of variation were lumbago and sciatica with lumbar spine insufficiency. This occurred more often in the probands than in the controls and even more often among females than males. The subjects with variations proved to be significantly older than those with consistent symptoms. Variations with lumbar spine insufficiency were rather unusual up to the age of 30—39 years after which the frequency increased. Variations with insufficiency caused most of the recurrences in both the probands and the controls. In this group there were 87 per cent of the subjects who complained only of persisting lumbar spine disorders.

Other variations than with lumbar spine insufficiency were uncommon in all the groups. The predominance of probands and the number of individuals increasing with age acted in the same way as those who had variation with lumbar spine insufficiency. In the higher ages nearly all the probands and controls with symptoms had lumbar spine insufficiency irrespective of which type of disease they had from the beginning.

A comparison between different types of lumbar spine disorders in 1967 revealed as a rule that those belonging to the lumbago group were free of symptoms and those belonging to the insufficiency group mostly had symptoms. Those with consistent types of lumbar spine disease mostly had no symptoms as compared to those with variations. Males had less symptoms than females.

The series was subjected to a study of symptoms from the cervical and thoracic spine. A significantly higher frequency of probands than controls had experienced cervical spine symptoms earlier (50.5% against 38.2%).

Thoracic spine symptoms occurred rarely in the past history (23.1% of probands and 17.9% of controls). 12.7 per cent of the probands and 11.3 per cent of the controls stated that they had suffered from cervical and thoracic symptoms earlier. The onset of cervical spine symptoms occurred about six years later than the lumbar spine disorders. The thoracic spine disorders mostly began at the

same time as the lumbar spine disorders Brachialgia was found in 30.9 per cent of the probands and in 25.4 per cent of the controls with cervical spine symptoms Radiating pain in those with thoracic spine symptoms was found only in 9.7 per cent of the probands and in 11.3 per cent of the controls

Similar to the lumbar spine, symptoms of the insufficiency type also occurred in the cervical and thoracic spine and were defined as a sensation of tiredness weakness stiffness and dull pain with varying degrees of pain duration and depending on strain Longstanding cervical and thoracic spine disorders of the insufficiency type occurred more often than singular acute attacks There was, however, only a significant deviation in the combination of cervical and thoracic spine symptoms found both in the probands and the controls

Combinations of various types of symptoms in different portions of the spine mostly occurred in the group with lumbar spine insufficiency and furthermore the number of insufficiency cases in other regions of the spine showed the highest frequency in this group As a rule less controls had symptoms in the cervical and the thoracic spine than the probands Contrary to this the controls belonging to the group with sciatica and lumbar spine insufficiency more often had insufficiency in the cervical and thoracic spine than the probands More females than males had symptoms in the cervical and thoracic spine both with insufficiency types and singular attacks

The probands with lumbar spine insufficiency and variations with lumbar spine insufficiency who also had insufficiency in the cervical or the thoracic spine had a significantly greater number of recurrences of lumbar spine disorders which however were not caused by age A statistically significant greater frequency of lumbar spine disorders at the examination in 1967 with symptoms in all three spinal areas occurred more often as compared to the other probands The mean number of sick listing periods and sick days was also higher in this group than in the other probands

Both among the probands and the controls the variations in the shape of the spine did not illustrate previous or existing spinal symptoms Painful palpation over the spinal process was more often noted in the probands than the controls both among those with earlier symptoms and those with symptoms at the examination However the method is subjective and therefore cannot be regarded as reliable Reduced mobility painful movements and positive Lasègues sign resulted in significant deviations only in comparison between those without symptoms and those with symptoms at the examination Neurological disturbances revealed not only existing symptoms but also earlier attacks of sciatica There were seldom neurological disturbances in the upper extremities

No correlation was carried out between lowered pelvis $>1-2$ cm or other changes in the lower extremities and previous or existing lumbar spine disorders found on examination

Röntgenological findings from the lumbar and thoracic spine showed that

disc degeneration and spondylosis depended on age. Changes which in the younger age groups were localized merely to the lumbar or the thoracic spine became aggravated and more extensive in the ages exceeding 50 years. Disc degeneration and spondylosis do not confirm the character of the lumbar spine disease but suggest the possibility of earlier attacks which possibly may have resulted in sick listing. Of other changes in the vertebrae only spondylolisthesis and spondylolysis occurred in a statistically significant greater frequency among controls with spinal disorders as compared to those without earlier symptoms but also with higher frequencies among the controls than the probands. Symmetrical and asymmetrical transitional vertebrae occurred more often among subjects without earlier symptoms than among those with symptoms and, therefore cannot be regarded as the cause of earlier and existing low back pain.

same time as the lumbar spine disorders Brachialgia was found in 30.9 per cent of the probands and in 25.4 per cent of the controls with cervical spine symptoms Radiating pain in those with thoracic spine symptoms was found only in 9.7 per cent of the probands and in 11.3 per cent of the controls

Similar to the lumbar spine symptoms of the insufficiency type also occurred in the cervical and thoracic spine and were defined as a sensation of tiredness weakness stiffness and dull pain with varying degrees of pain duration and depending on strain Longstanding cervical and thoracic spine disorders of the insufficiency type occurred more often than singular acute attacks There was, however only a significant deviation in the combination of cervical and thoracic spine symptoms found both in the probands and the controls

Combinations of various types of symptoms in different portions of the spine mostly occurred in the group with lumbar spine insufficiency and furthermore the number of insufficiency cases in other regions of the spine showed the highest frequency in this group As a rule less controls had symptoms in the cervical and the thoracic spine than the probands Contrary to this the controls belonging to the group with sciatica and lumbar spine insufficiency more often had insufficiency in the cervical and thoracic spine than the probands More females than males had symptoms in the cervical and thoracic spine both with insufficiency types and singular attacks

The probands with lumbar spine insufficiency and variations with lumbar spine insufficiency who also had insufficiency in the cervical or the thoracic spine had a significantly greater number of recurrences of lumbar spine disorders which however were not caused by age A statistically significant greater frequency of lumbar spine disorders at the examination in 1967 with symptoms in all three spinal areas occurred more often as compared to the other probands The mean number of sick listing periods and sick days was also higher in this group than in the other probands

CHAPTER 1

INTRODUCTION

This work is part of a research into the longitudinal growth of bones against the clinical background of leg length disparity in children. Hundreds of publications have appeared during the last century describing different conditions resulting in stimulated or retarded growth in length. The clinical aspect of this problem was reviewed by Goff in 1960 citing 638 references on the topic. The acceleration of growth in length reported during the last century after fractures, osteomyelitis or arterio-venous fistulae in limbs has led to series of experimental efforts to induce increased growth rate for therapeutic equalizing of leg length disparity caused by one-sided stimulation as mentioned or by retardation after poliomyelitis, epiphyseal growth plate injuries or congenital defects. These experiments were recently reviewed and analysed by Sandén (1967) in a table listing about 120 papers. Periosteal stripping, curettage of the medullary cavity, implantation of a great number of different materials into the medullary cavity, plugging of the cavity, fracturing of bones, application of heat, electricity, roentgen radiation, ultrasound, shortwave diathermy, venous stasis, creation of femoral arterio-venous fistulae, immobilization, nerve sectioning, nerve root sectioning, sympathectomy and mechanical stress and strain have all been tried. Summarizing these observations there is no doubt that direct trauma to the growing long bones, whether caused by fracture, periosteal stripping or medullary plugging (Hansson 1967) does cause a certain longitudinal growth acceleration in a considerable percentage of cases, except when the epiphyseal growth plate itself is injured or the trauma is minimal. The same applies to chronic inflammation, whether caused by infection, rheumatoid arthritis (Brattström 1963), implantation of foreign materials or other necrotizing influences. Finally, indirect measures such as arterio-venous fistulae and peripheral nerve divisions have shown an enhancement of growth in length (Sandén 1967) while induced venous stasis has produced more diverging results.

CHAPTER 1

INTRODUCTION

This work is part of a research into the longitudinal growth of bones against the clinical background of leg length disparity in children. Hundreds of publications have appeared during the last century describing different conditions resulting in stimulated or retarded growth in length. The clinical aspect of this problem was reviewed by Goff in 1960 citing 638 references on the topic. The acceleration of growth in length reported during the last century after fractures, osteomyelites or arterio-venous fistulae in limbs has led to series of experimental efforts to induce increased growth rate for therapeutic equalizing of leg length disparity caused by one sided stimulation as mentioned or by retardation after poliomyelitis, epiphyseal growth plate injuries or congenital defects. These experiments were recently reviewed and analysed by Sanden (1967) in a table listing about 120 papers. Periosteal stripping, curettage of the medullary cavity, implantation of a great number of different materials into the medullary cavity, plugging of the cavity, fracturing of bones, application of heat, electricity, roentgen radiation, ultrasound, shortwave diathermy, venous stasis, creation of femoral arterio-venous fistulae, immobilisation, nerve sectioning, nerve root sectioning, sympathectomy and mechanical stress and strain have all been tried. Summarizing these observations there is no doubt, that direct trauma to the growing long bones, whether caused by fracture, periosteal stripping or medullary plugging (Hansson 1967) does cause a certain longitudinal growth acceleration in a considerable percentage of cases except when the epiphyseal growth plate itself is injured or the trauma is minimal. The same applies to chronic inflammation, whether caused by infection, rheumatoid arthritis (Bratt 1963) implantation of foreign materials or other localizing influences. Finally indirect measures, such as arterio-venous fistulae and peripheral nerve divisions, have shown an enhancement of growth in length (Sanden 1967) while induced venous stasis has produced more diverging results.

Arterial hyperaemia

The underlying cause of longitudinal over growth is mostly considered to be increased arterial blood flow in the growth plate regions (*Langenskiöld 1957, Hansson & Wiberg 1963 Vanderhoeft et al 1963*) This should apply during fracture healing (*Levander 1929*) and after periosteal loosening of a diaphysis (*Ollier 1867, Brodin 1955 Elo 1960*) as well as after experimental interruption of the intramedullary vessels (*Ferguson 1933*) By blocking the medullary canal (*Cavadias & Trueta 1965*) this interruption is made more lasting and will cause a compensatory increase in blood flow to the metaphysis through vessels near the growth plate thereby inducing an increased growth rate Also when the femoral arterio venous fistula was introduced as a measure for growth stimulation the effect was believed to be mediated through a hyperaemia distal to the fistula (*Janes & Musgrove 1950*) Later studies on the actual blood flow in these cases have however shown a decreased blood flow distally (*Holman 1955*) Registration of growth in length and of the blood flow in bone under the same circumstances was made by *Sunden (1967)* He demonstrated an increased growth after peripheral nerve division measured by oxytetracycline labelling, and a simultaneous increase in bone blood flow measured as heat clearance This is in support of the hyperaemia theory further strengthened by the fact that the same growth acceleration was achieved by immobilisation through Achilles tendon division in rabbits as well Immobilisation in plaster of rabbit legs has been shown to cause an increase in pO_2 and pH of the intramedullary blood as well as an increased Sr^{85} clearance (*Semb 1966*) which also favours the hyperaemia theory The important role played by the skeletal blood flow has also led to successive attempts to stimulate growth in length by direct implantation of a patent artery into a long bone (*Dickerson 1966*)

Venous stasis

The major opposition to the theory of arterial hyperaemia has come from authors believing a venous stasis to be the causative agent in cases of one sided over growth in length This should be the mechanism with trauma to a long bone as well as in femoral arterio venous fistulae and in venous stasis induced by tourniquet (*Hutchison & Burdeaux 1954*) Arterio venous fistula is the most reliant stimulant of growth experimentally and clinically generally leading to a more reliable increase in length than trauma and inflammation (*Broca 1856 Janes & Musgrove 1950 Cooley et al 1960, Hierton 1961 Janes &*

Jennings 1961) Birnstingl (1962) reported 23 cm increase in the femur and 43 cm increase in the tibia in a case of a femoral fistula demonstrated by serial femoral angiography. He considered this dominating tibial growth acceleration to be supportive evidence for the hypothesis that venous stasis caused by the fistula, was the causative mechanism. This opinion seems to be shared by Colt & Iger (1963) and by Keck & Kelly (1964) who angiographically demonstrated an arterial back flow in the distal vein they called this an active venous stasis. The haemodynamics of arterio-venous fistulae have been subjected to several investigations (Holman 1955 Henrie et al 1959 Hillman et al 1959 Stein et al 1959 Ingebrigtsen et al 1963 Weinman et al 1964). Venous stasis distally is a common finding although the collateral circulation which is very pronounced and the back flow in the veins both complicate the interpretation regarding effects on the growth plates. Hillman et al (1959) conclude about induced stasis and arterio-venous fistulae "venous stasis is the common denominator in these two conditions which produce limb overgrowth and would seem to be related etiologically. The exact mechanism by which venous stasis produces limb over growth is still unexplained. Venous stasis induced for therapeutic purposes was first reported by Helferich (1887) who claimed to have reduced leg inequality in two children by prolonged tourniquet stasis of the shorter legs. The method was repeated later in humans (Bier 1933) and in animal experiments (Borel 1922 Aishikawa 1936 Peck 1957 Colt & Iger 1963 Keck & Kelly 1964) with diverging results. In 1948 Servelle published a series of venographically verified unilateral congenital venous abnormalities with stasis in 14 humans whose affected legs were 0.8—9.6 cm longer than the contralateral ones while no differences could be found in any of 25 patients with chronic lymphoedema elephantiasis. Hutchison & Burdeaux (1954) are among those who found induction of venous stasis to stimulate the growth rate. They express the opinion that venous stasis is responsible for the over growth not only in arterio-venous fistulae but also in fractures and osteomyelites. Attempts to measure the actual blood flow in bone during venous stasis have been contradictory (Shaw 1964 Walderrama & Trueta 1965 White & Stein 1965).

Growth stimulating substances

No successful efforts seem to have been made to demonstrate the mechanism by which a venous stasis is supposed to accelerate the growth. Foster & Airtley (1959) believe that possibly the stasis supplies an increase of growth stimulating substances. This has also been proposed as a mechanism in other conditions with over growth of bones (Lacroix 1947 Wray & Goodman 1961). Even when dealing with leg length inequality as here one must not forget the possibility of

Mechanism of overgrowth

Arterial hyperaemia

The underlying cause of longitudinal over growth is mostly considered to be increased arterial blood flow in the growth plate regions (*Langenskiöld 1957, Hansson & Wiberg 1963 Vanderhoeft et al 1963*) This should apply during fracture healing (*Lerander 1929*) and after periosteal loosening of a diaphysis (*Ollier 1867 Brodin 1955, Elo 1960*) as well as after experimental interruption of the intramedullary vessels (*Ferguson 1933*) By blocking the medullary canal (*Cavadias & Trueta 1965*) this interruption is made more lasting and will cause a compensatory increase in blood flow to the metaphysis through vessels near the growth plate, thereby inducing an increased growth rate Also when the femoral arterio venous fistula was introduced as a measure for growth stimulation the effect was believed to be mediated through a hyperaemia distal to the fistula (*Janes & Musgrove 1950*) Later studies on the actual blood flow in these cases have however, shown a decreased blood flow distally (*Holman 1955*) Registration of growth in length and of the blood flow in bone under the same circumstances was made by *Sunden (1967)* He demonstrated an increased growth after peripheral nerve division measured by oxytetracycline labelling and a simultaneous increase in bone blood flow measured as heat clearance This is in support of the hyperaemia theory further strengthened by the fact that the same growth acceleration was achieved by immobilisation through Achilles tendon division in rabbits as well Immobilisation in plaster of rabbit legs has been shown to cause an increase in pO₂ and pH of the intramedullary blood as well as an increased Sr⁸⁹ clearance (*Semb 1966*) which also favours the hyperaemia theory The important role played by the skeletal blood flow has also led to successive attempts to stimulate growth in length by direct implantation of a patent artery into a long bone (*Dickerson 1966*)

Venous stasis

The major opposition to the theory of arterial hyperaemia has come from authors believing a venous stasis to be the causative agent in cases of one sided over growth in length This should be the mechanism with trauma to a long bone as well as in femoral arterio venous fistulae and in venous stasis induced by tourniquet (*Hutchison & Burdeaux 1954*) Arterio venous fistula is the most reliant stimulant of growth experimentally and clinically, generally leading to a more reliable increase in length than trauma and inflammation (*Broca 1856 Janes & Mugrove 1950 Cooley et al 1960 Hierton 1961 Janes &*

Jennings 1961) Birnstingl (1962) reported 2.3 cm increase in the femur and 4.3 cm increase in the tibia in a case of a femoral fistula demonstrated by serial femoral angiography. He considered this dominating tibial growth acceleration to be supportive evidence for the hypothesis that venous stasis caused by the fistula was the causative mechanism. This opinion seems to be shared by Colt & Iger (1963) and by Keck & Kelly (1964) who angiographically demonstrated an arterial back flow in the distal vein; they called this an active venous stasis. The haemodynamics of arterio-venous fistulae have been subjected to several investigations (Holman 1955, Henrie et al 1959, Hillman et al 1959, Stein et al 1959, Ingebrigtsen et al 1963, Weinman et al 1964). Venous stasis distally is a common finding although the collateral circulation which is very pronounced and the back flow in the veins both complicate the interpretation regarding effects on the growth plates. Hillman et al (1959) conclude about induced stasis and arterio-venous fistulae: venous stasis is the common denominator in these two conditions which produce limb overgrowth and would seem to be related etiologically. The exact mechanism by which venous stasis produces limb over growth is still unexplained. Venous stasis induced for therapeutic purposes was first reported by Helferich (1887) who claimed to have reduced leg inequality in two children by prolonged tourniquet stasis of the shorter legs. The method was repeated later in humans (Bier 1903) and in animal experiments (Borel 1922, Kishikawa 1936, Peck 1957, Colt & Iger 1963, Keck & Kelly 1964) with diverging results. In 1948 Servelle published a series of venographically verified unilateral congenital venous abnormalities with stasis in 14 humans whose affected legs were 0.8–9.6 cm longer than the contralateral ones while no differences could be found in any of 25 patients with chronic lymphoedema elephantiasis. Hutchison & Burdeaux (1954) are among those who found induction of venous stasis to stimulate the growth rate. They express the opinion that venous stasis is responsible for the over growth not only in arterio venous fistulae but also in fractures and osteomyelites. Attempts to measure the actual blood flow in bone during venous stasis have been contradictory (Shaw 1964, Walderrama & Trueta 1965, White & Stein 1965).

Growth stimulating substances

No successful efforts seem to have been made to demonstrate the mechanism by which a venous stasis is supposed to accelerate the growth. Foster & Kirtley (1959) believe that possibly the stasis supplies an increase of growth stimulating substances. This has also been proposed as a mechanism in other conditions with over growth of bones (Lacroix 1947, Wray & Goodman 1961). Even when dealing with leg length inequality as here one must not forget the possibility of

Mechanism of overgrowth

Arterial hyperaemia

The underlying cause of longitudinal over growth is mostly considered to be increased arterial blood flow in the growth plate regions (*Langenskiöld 1957, Hansson & Wiberg 1963, Vanderhoeft et al 1963*) This should apply during fracture healing (*Levander 1929*) and after periosteal loosening of a diaphysis (*Ollier 1867, Brodin 1955, Elo 1960*) as well as after experimental interruption of the intramedullary vessels (*Ferguson 1933*) By blocking the medullary canal (*Cavadias & Trueta 1965*) this interruption is made more lasting and will cause a compensatory increase in blood flow to the metaphysis through vessels near the growth plate thereby inducing an increased growth rate Also when the femoral arterio venous fistula was introduced as a measure for growth stimulation the effect was believed to be mediated through a hyperaemia distal to the fistula (*Janes & Musgrove 1950*) Later studies on the actual blood flow in these cases have however shown a decreased blood flow distally (*Holman 1955*) Registration of growth in length and of the blood flow in bone under the same circumstances was made by *Sunden (1967)* He demonstrated an increased growth after peripheral nerve division measured by oxytetracycline labelling and a simultaneous increase in bone blood flow, measured as heat clearance This is in support of the hyperaemia theory, further strengthened by the fact that the same growth acceleration was achieved by immobilisation through Achilles tendon division in rabbits as well Immobilisation in plaster of rabbit legs has been shown to cause an increase in pO₂ and pH of the intramedullary blood as well as an increased Sr⁸⁵ clearance (*Semb 1966*) which also favours the hyperaemia theory The important role played by the skeletal blood flow has also led to successive attempts to stimulate growth in length by direct implantation of a patent artery into a long bone (*Dickerson 1966*)

Venous stasis

The major opposition to the theory of arterial hyperaemia has come from authors believing a venous stasis to be the causative agent in cases of one sided over growth in length This should be the mechanism with trauma to a long bone as well as in femoral arterio venous fistulae and in venous stasis induced by tourniquet (*Hutchison & Burdcaux 1954*) Arterio venous fistula is the most reliant stimulant of growth experimentally and clinically generally leading to a more reliable increase in length than trauma and inflammation (*Broca 1856, Janes & Musgrove 1950, Cooley et al 1960, Hierton 1961, Janes &*

affecting living cells. Physical variation of either or both of these might influence the rate of growth of bone. They observed an increased growth in length in both dogs and rats using an electrically heated sling around the femora, but unfortunately the method produced such a necrotizing effect that even fractures resulted. Heating was attempted also by Ring & Lee (1958) using carbon resistors implanted into the bony epiphysis of the ulna in rabbits but they induced only increase in width.

The importance of the temperature factor has thus been observed but no conclusive results have been presented as to the possibilities of using it for growth rate alterations.

The oxygen factor

Concerning the possibilities of inducing changes in the growth of long bones by alteration of the oxygen tension no reports can be found in the literature. In spite of this many authors mention increase in oxygen availability as a probable factor in observed accelerations in bone growth. Since the discovery of oxygen by Priestley in 1774 much has been written regarding oxygen in medicine. This literature has been reviewed by Beart (1945, 1964) and with regard to the use of oxygen at increased barometric pressure also by Linehan (1964) and by Jacobson et al (1965). The fundamental importance of oxygen in general has even led to trials of injection of gaseous oxygen in arteries in conditions of ischaemia (Fey & Boxberg 1956) as well as injection of diluted hydrogen peroxide but not in connection with growth studies.

Tissue culturing techniques have been employed to study oxygen effects on growth in general. Cooper et al (1958) studied the growth of animal cells and virus. Olloart & Blair (1965) demonstrated increased growth of bacteria in oxygen tensions up to 1 atm abs (atmosphere absolute = 760 mm Hg) and bacteriostasis on further increase of the oxygen tension. Nelson (1958) studied the early development of chick and frog embryos and recorded some stimulation in certain stages. Goldhaber (1958) observed increased osteoclastic activity of cultured bone at 95 per cent oxygen in the gaseous phase at 1 atm abs and pointed out the similarity to the effects caused by parathyroid hormone. Vaes & Nicols (1962) found increased metabolism in rat bone cultures at increased oxygen tension. Shaw & Basset (1967) cultured chick embryo tibiae under different oxygen concentrations in the gaseous phase and found maximal osteogenesis at 35 per cent but at 5 per cent and at 95 per cent of oxygen there was a pronounced decrease in osteogenesis and chondrogenesis.

The effects of increased oxygen tension on healing of standardized surgical wounds have been studied by Lundgren & Sandberg (1965) reporting decreased healing in normal rats and acceleration in anemic rats during hyperbaric

local liberation of stimulating substances of the same type as in cases of total body growth aberrations, that is hormonal and nutritional factors, but acting locally

Pressure and tension

For completeness it is necessary to mention also mechanical loading and unloading as measures to influence growth of bones although this has very little application in this investigation. The temporary epiphyseodesis with staples according to Blount (*Blount & Clarke 1949*) is proof of the growth retarding possibilities using pressure, demonstrated previously by *Wegner (1878)* also using staples and wire cerclage. The pressure necessary to stop growth has been determined (*Strobino et al 1952, Blount & Zetter 1952*). The possibility that growth can be accelerated by tension has not been demonstrated convincingly (*Smith & Cunningham 1957*).

Increase in temperature

The living cell and its enzymatic, oxidative systems, must have some optimal temperature and oxygen tension for the physiological processes to proceed normally. As over growth can be induced there might be a zone left on the side of the normal temperature or oxygen tension where an increased turn over could take place. The temperature factor has been paid attention to in the literature. Supposing increase in temperature to be a common denominator for all conditions of over growth mentioned above *Granberry & Janes (1963)* tried to heat a growth plate in dogs by microwave diathermy but with no positive result. On the other hand *Doyle & Smart (1963)* observed increased growth in rats after short wave diathermy and so did *Asnoub (1958)* by housing mice for 4 weeks at two extreme temperatures recording an increase in tail length of 15 per cent in the warmer environment.

After creating arterio venous fistulae *Janes & Musgrove (1950)* observed increased longitudinal bone growth in dogs and they recorded an increased medullary temperature in the femur of the operated legs compared to the unoperated. *Brodin (1955)* measured the intramedullary temperature in the tibia after one sided periosteal loosening but observed a temperature variation within the cavity of such a magnitude that side comparisons were impossible. *Richards & Stofer (1959)* also tried to study the temperature factor. They say temperature and oxygen tension are probably the two most important physical variables

and carbon dioxide changes which have to be considered during change in the environmental oxygen tension. Regarding the controversial opinions about hyperaemia or venous stasis as the responsible factor for accelerated growth in length it has been considered to be of great interest to see whether a direct alteration in the respiratory oxygen tension can induce a change in the growth rate especially as the oxygen factor itself on the cellular plane must be of a key importance, not earlier studied in this respect. Except for the oedema promoting tendency a major character of venous stasis compared to arterial hyperaemia is probably the lower tissue tension of oxygen and higher tension of carbon dioxide and consequently a study of the influence of these gases on growth could shed some light on the problem of overgrowth of bones increasing our knowledge about oxygen therapy in general and about the physiology of the growing epiphyseal plate in particular.

oxygen therapy at intervals, but in dogs augmented healing has been reported (Beckham & Hitchcock 1965). Studying the survival of split skin grafts in 48 humans Perrins (1967) recorded an increase in the taken area of 29 per cent and an increase in complete graft taking from 17 to 64 per cent after hyperbaric oxygenation at 2 atm abs of pure oxygen breathing for two hours twice daily during three days after operation.

Also in the case of fracture healing oxygen has lately aroused interest. Coulson et al (1966) report accelerated healing in femoral fractures of the rat at hyperbaric oxygenation in intervals for 1–3 weeks, tested by mechanical resistance and radioactive calcium activity. This finding is complemented by Makley et al (1967) observing impaired healing of fractures in rats at reduced barometric pressure corresponding to 18 000 feet of altitude. Periosteal proliferation in mice has been studied by Manspeizer & Tonna (1967) who found decreased proliferation at 5 per cent oxygen and increased at 100 per cent oxygen in the environment measured by tritiated thymidine and autoradiography. A search of the literature has actually revealed one work mentioning also growth in length and the influence of increased oxygen tension and that is Wright & Howard Flanders (1957) investigating the growth in length of mice tails after roentgen radiation combined with 100 per cent of oxygen in an environment of atmospheric pressure varying from 0.1 to 3.0 atm abs. They found radiosensitivity decreased during hypoxia and increased during hyperoxia as measured by the length of the tails. In a control group they varied the oxygen tension without radiation and did not observe any effects on the length of the tails. The data given and the short period of treatment do not allow any conclusions to be drawn concerning the unplanned observations on the relationship between longitudinal growth of bones and the environmental partial pressure of oxygen.

Purpose of investigation

The purpose of this investigation can now be advanced in the light of what is said above, concerning factors influencing longitudinal bone growth especially the oxygen factor. In the literature on over growth of bones increase in the oxygen tension is almost regularly mentioned as a hypothetic cause of the growth stimulation but no experimental efforts to prove this have appeared. Preliminary observations on change in the longitudinal growth of the proximal tibial metaphysis of rabbits during hyperbaric oxygenation for repeated short intervals during a single day have been published earlier (Persson 1967) and the aim has been to extend the study for more exact documentation of the effects and for evaluation of such secondary consequences, as oxygen toxicity

couple of days before the experiments. The hutches were in door with daylight, with electric light added during winter between about 07 00 and 17 00. The temperature in the hutches was about 18—23°C. Humidity was not specially controlled. The rabbits were fed on pellets and water ad libitum and by milk from their mothers as long as they suckled them. During the 8 hrs of treatment (see later) both test and control rabbits were taken away from the mothers but were given pellets and water in the treatment boxes. They were weighed on the first and on the last day of the experiment.

After the choice of rabbits to be used for the study one had to consider which aberrant animals to exclude during the experiments.

Exclusion of animals

Among young rabbits at the time of weaning a considerable percentage will die or be temporarily diseased. Further more some of them will be regaining health during the time of growth measurements and this will give an increased deviation in the figures of growth making necessary very long series unless these factors could be reduced in a way not influencing the reliability of the effects to be studied. This problem is of special importance when growth rate investigations are performed for studying influences on the whole rabbit, comparing different individuals in comparison to right and left side studies in the same animal. This is consequently an added difficulty but the method used in this way allows for increased possibilities. The preliminary studies (Persson 1967) had shown that some principles had to be introduced for exclusion of unhealthy animals because even grossly undetectable diseases in the rabbits could severely affect the growth rates recorded. It was thought unsatisfactory in this investigation to exclude animals below a certain weight (Hansson 1967) as different breeders could have different standard weights at a certain age because of genetic or nutritional factors. It was also thought insufficient to exclude animals because of clinical impression of disease (Hansson 1967, Sundén 1967) and after the preliminary experiences the following conditions for excluding animals were adopted:

- 1 Spontaneous death during the experiment (only complete observation series were used)
- 2 Loss of weight between the start and the end of the experiment (precision of the instrument ± 5 grams)
- 3 Diarrhoea observed during the experiment
- 4 Unacceptable quality of preparations for microscopy (allowing for less than 5 readings)

MATERIAL AND METHODS

Choice of animal

Because of the toxicity of pure oxygen inhaled for an extended period it was evident that the method chosen, should allow determination of growth rates with a high accuracy over very short periods of time that is about one day. Therefore the intravital tetracycline labelling method seemed to be the best for quantitative measurements (see later). Concerning the choice of animal it was clear that it had to be some relatively fast growing type to allow observations on changes during the short times made possible by the oxygen toxicity and secondly, it had to be easily available for the comparatively long series necessary, in a study dealing with comparisons between different animals and not as hitherto for the above mentioned method between the right and left sides. These conditions allow for the use of rabbits rats mice and guinea pigs but as the method hitherto had been used for longitudinal growth estimations mainly in rabbits, (Hulth & Olerud 1962 Hansson 1964 and 1967 Sundén 1967) this favoured the choice of rabbits, especially as they had often been used in bone growth investigations in general as well as in the literature on oxygen toxicity and breathing physiology (Dittmer & Grebe 1958). The rabbits used were always white to make the intravenous injections easier in the young animals used aged between 27 and 42 days at the day of treatment. The age was chosen because of the easier preparation and the greater growth rate during this time (Hansson 1967). The sex of the animal was not taken into account (Hansson 1967).

Care of animals

The general care of animals was the same in test and control as follows. Rabbits were bought from three breeders who had noted the day of birth and were transported to the hutches with their mothers. They lived together for a

- 5 Disease made evident by abnormal growth rate, defined as being more than 100 microns below the arithmetic mean of litter mates exposed to the same treatment (observed during any of the three 24 hrs periods measured)
- 6 Animal left single in a litter after exclusions above

(For definitions of preparations readings and growth periods see later in this chapter)

These six principles have been followed throughout the investigation with the following comments. Regarding point 1 there are no exceptions complete readings were made impossible by the death of the animal. Point 2 has proved to be well founded on the fact that decreased growth rate was practically always observed in animals with decrease in weight and after some time these animals were not prepared for microscopy at all. Point 3 was used in the way that animals being soiled by their diarrhoea were excluded. Regarding point 4 30 animals were accepted in the beginning of the investigation with less than five readings, but only in cases where no difference between consecutive time periods were recorded. With regard to point 5 finally, 2 animals were accepted also in the beginning and in cases where the difference between consecutive periods was not more than 10 microns, thereby negligibly affecting the calculations. A full account of excluded animals is given in Table 1. Each animal is given with its identification number the last letter plus the following roman figures designating the number within its litter and the first one or two letters designating the litter. This allows one in reading the tables, given in the results to identify the origin of the excluded animals. The total number of excluded animals is 148 but this should be compared to the total number of animals before this exclusion that is 1079 giving a reasonable percentage of exclusion for rabbits at this age. In all 13 animals died spontaneously after registration at the institution but before any treatment and are therefore not listed in Table 1. The distribution of animals given in Table 1 further shows that spontaneous deaths were more common among test animals, of which 4 died during administration of the maximal doses of oxygen and 4 while given the minimum doses. This is further discussed later. In the group of unacceptable preparations there are also more test animals but the distribution is even over the whole material comprising 532 tests and 399 controls. In the other groups there is no remarkable difference between the number of test and control animals excluded.

From the studies of *Hansson (1967)* it was known that there was a successive decrease in growth rate after the age of 30 days (Fig. 15) but no correlation between weight and growth within each litter. It was therefore considered to be of interest to see how the selection principles used in this study influenced on a possible correlation between these factors. There was a considerable number of control animals with notes on age weight and growth in length of the proximal tibial metaphysis measured on the same day as they were weighed. In all 237 animals were grouped according to age and analysed regarding a correlation between growth and weight at the given age. It turned out to be a

These six principles have been followed throughout the investigation with the following comments. Regarding point 1, there are no exceptions complete readings were made impossible by the death of the animal. Point 2 has proved to be well founded on the fact that decreased growth rate was practically always observed in animals with decrease in weight and after some time these animals were not prepared for microscopy at all. Point 3 was used in the way that animals being soiled by their diarrhoea were excluded. Regarding point 4, 30 animals were accepted in the beginning of the investigation with less than five readings but only in cases where no difference between consecutive time periods were recorded. With regard to point 5 finally, 2 animals were accepted also in the beginning and in cases where the difference between consecutive periods was not more than 10 microns thereby negligibly affecting the calculations. A full account of excluded animals is given in Table 1. Each animal is given with its identification number the last letter plus the following roman figures designating the number within its litter and the first one or two letters designating the litter. This allows one in reading the table, given in the results to identify the origin of the excluded animals. The total number of excluded animals is 148, but this should be compared to the total number of animals before this exclusion, that is 1079, giving a reasonable percentage of exclusion for rabbits at this age. In all 13 animals died spontaneously after registration at the institution but before any treatment, and are therefore not listed in Table 1. The distribution of animals given in Table 1 further shows that spontaneous deaths were more common among test animals of which 4 died during administration of the maximal doses of oxygen and 4 while given the minimum doses. This is further discussed later. In the group of unacceptable preparations there are also more test animals but the distribution is even over the whole material comprising 532 tests and 399 controls. In the other groups there is no remarkable difference between the number of test and control animals excluded.

From the studies of Hansson (1967) it was known that there was a successive decrease in growth rate after the age of 30 days (Fig 15) but no correlation between weight and growth within each litter. It was therefore considered to be of interest to see how the selection principles used in this study influenced on a possible correlation between these factors. There was a considerable number of control animals with notes on age weight and growth in length of the proximal tibial metaphysis measured on the same day as they were weighed. In all 237 animals were grouped according to age and analysed regarding a correlation between growth and weight at the given age. It turned out to be a

longitudinal growth during three consecutive time periods. Further injections had shown an increasing indefiniteness of line identification in the microscopical sections because of reabsorption and remodelling of the bone trabeculae of the metaphysis (Fig. 1). The doses of oxytetracycline was 10—15 mg/kg body-weight being without toxic effect on growth in length (Hansson 1967). The gas exposures were made in defined time relation to the oxytetracycline injections (Fig. 2 and 3). Within half an hour after the fourth injection the animals were killed by intravenous injection of Evipan® (Bayer) about 100 mg/kg body weight. The left proximal tibia was removed, chosen because of its high growth rate in combination with the comparatively flat shape of its epiphyseal growth plate (Hansson 1967). For this investigation of changes in growth during exposure

positive correlation which was highly significant in three age groups and insignificant in eight age groups. When the groups were put together as listed below in 5 day groups it was significant in all the groups implying a greater daily growth in length at a higher weight.

Age in days	Number	r value	t value
26—30	116	0.39	4.53***
31—35	93	0.32	3.21**
36—40	28	0.78	6.32***
total	237	0.17	2.64**

It is notable that the significance of correlation in the total material is smaller than in any of the age groups, which means that a negative factor increases by the fact that an older animal grows less than a younger after the age of 30 days (Fig. 15). It was assumed that the day of birth was not noted by the breeder with a higher accuracy than one or two days. This made it reasonable to use the 5 day groups above. The demonstrated correlation between weight and growth in this material was not of consequence in the present study, because this was based on differences in growth between consecutive days in the same animal, and with littermates in test and control groups. These were made with an approximately even distribution of weights.

Method for measuring of growth

The reasons for selecting the intravital oxytetracycline labelling method for this investigation are mentioned in the beginning of this chapter. Since the discovery by Andre (1956) that tetracyclines are deposited in bone tissue this has been further studied by Milch et al. (1958). The method was used for lamellar bone growth measurements only (see Hansson 1967) until it was shown that tetracyclines were deposited in the border between the metaphysis and the growth plate marking the endochondral longitudinal bone growth as well (Hulth & Olerud 1962). These possibilities were developed and used by Hansson (1964 and 1967) also reviewing the earlier literature. In this investigation the oxytetracycline technic has been used as described below according to Hansson.

The rabbits were given oxytetracycline (Terramycin® Pfizer) intravenously in a marginal ear vein 4 times each, at intervals of 24 hrs \pm 5 minutes. In a smaller part of the investigation the injections were given with intervals of 12 hrs, \pm 25 minutes. These four injections allowed the determination of

longitudinal growth during three consecutive time periods. Further injections had shown an increasing indefiniteness of line identification in the microscopical sections because of reabsorption and remodelling of the bone trabeculae of the metaphysis (Fig. 1). The doses of oxytetracycline was 10–15 mg/kg body weight being without toxic effect on growth in length (Hansson 1967). The gas exposures were made in defined time relation to the oxytetracycline injections (Fig. 2 and 3). Within half an hour after the fourth injection the animals were killed by intravenous injection of Evipan® (Bayer) about 100 mg/kg body weight. The left proximal tibia was removed chosen because of its high growth rate in combination with the comparatively flat shape of its epiphyseal growth plate (Hansson 1967). For this investigation of changes in growth during exposure

of the whole animal to alteration of respiratory gas tensions no important advantage could be expected by utilizing more than one epiphyseal growth region. The piece of bone was fixed in concentrated ethanolum (99.5 per cent) for 12–72 hrs. The bony epiphysis was then horizontally divided near the growth plate and the diaphysis was sawed off as well about 5 mm distal to the plate. The resulting piece was sagittally cut in one lateral and one medial half, of which the lateral was used for sectioning. Parallel to the metaphyseal trabeculae seen in the sagittal cut surface the anterior quarter was cut off with a razor blade knife and the posterior quarter was used. In the new surface, the cut was again controlled or adjusted parallel to the planes of the trabeculae of the metaphysis on both the surfaces exposed. Further cutting of bone sections with the razor blade knife were made parallel to the trabecular system. The cutting was then made in the sagittal plane and about 10 sections were taken and put into Xylol for 5–10 minutes. The thickness was occasionally checked and ranged between 60–120 microns as measured with a micrometer screw gauge. Between 6 and 10 sections were then mounted in liquid DePeX (Gurr) on glass and covered with glass. After drying in darkness the sections were examined in an ultraviolet (mercury lamp OSRAM HBO 200 W) fluorescence microscope (Zeiss) with a dark field condensor (NA 0.65/0.85) and measured with a calibrated ocular (12.5 \times), the objective being 10 \times . The primary filters used were BG 12/4+BG 38/2.5 and the secondary filter 53. With this equipment the longitudinal growth rate was measured as three distances between the metaphyseal borders of the four lines in such a way that the readings were always made with the measuring scale projected along unbroken bone trabeculae in positions where they were nearly at right angles to the growth cartilage plate (Fig. 1). The error of this method has been determined earlier by side comparisons (Hansson 1967, Persson 1967, Sundén 1967). One or two readings were made on each section and all together about 5–10 readings were made. The arithmetic mean number of readings in each animal was 7.3 in the entire material. To be accepted readings should be possible along the same trabecula for all the three consecutive time periods used. For the further calculations the arithmetic means of these readings were used, giving in microns the longitudinal growth rates of the proximal tibial metaphysis during three consecutive periods of time. The first period before the gas treatment gave one control value to which the following growth changes could be referred. A second type of growth control value was achieved by using about half of each litter as a reference group simultaneously treated with air only. This gave a measure of possible growth effects caused by stress factors from change in housing and handling during the day of gas treatment and secondly it allowed for possibilities of double blind readings during microscopy with decodification of the identification numbers on the glasses made after the measuring.

Statistical methods

The statistical analysis was based on differences in growth between each of the three consecutive time periods measured in the same animal. In the group of animals where pure oxygen was tested it was specially analysed whether the statistical result was influenced by the fact that rounded figures were used in this investigation. The mean value of the readings in each animal at each time period was rounded off 466 was put to 470 for instance. This was done because the measuring stab of the microscope did give only two figures (Fig. 1). The analysis demonstrated that the statistical significances were uninfluenced by this measure. For each step of the investigation about 10–20 animals were exposed identically with a certain test gas and about the same number of animals to air as a control. In this way it was possible to follow the changes in growth within each animal after a certain exposure and after the air exposure and then to compare the differences of effects in the two samples. In the bottom of each table given in the chapters on results the arithmetic mean of growth in each time period is given as well as the mean difference between two consecutive time periods, the standard deviation of these differences, the *t* value with degrees of significance (*Student's test*) and the *n* value.

$$\text{standard deviation} = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (X - m)^2}$$

$$t \text{ value} = \frac{m_1 - m_2}{S_d \sqrt{n}} \quad \text{with } n-1 \text{ degrees of freedom}$$

The two sided alternative hypothesis was used in the Student's test as the direction of a possible change in growth could not be predicted. The test within the material of each table is given in its bottom but the tests between control groups and the test gas groups that is between two different tables are given in the corresponding text in each chapter. For this comparison the following test function was used again with a two-sided alternative hypothesis.

$$t = \frac{m - m_1 - (\mu_1 - \mu_2)}{S \sqrt{\frac{1}{n} + \frac{1}{n_1}}} \quad \text{with } n + n_1 - 2 \text{ degrees of freedom}$$

It was tested that the variables of the samples were normally or approximately normally distributed which is required for the test. It is also necessary that

the standard deviations of the populations are the same, which was tested by the function $F = \frac{S_x^2}{S_y^2}$ with $n_x - 1$ respectively $n_y - 1$ degrees of freedom. In some parts of the material this was not the case and then a non parametric test was used, namely Wilcoxon's rank sum test (T), or Mann-Whitney's test (U). In these cases T or U is written in the corresponding text.

In the interpretation of the results conventional probability levels have been used with the following symbols written

—	$p > 0.05$	(not significant)
×	$0.01 < p < 0.05$	(almost significant)
××	$0.001 < p < 0.01$	(significant)
×××	$p < 0.001$	(highly significant)

Abbreviations

$$\sum_{i=1}^n X_i = \text{the sum of the values of the observations (from 1 to } n)$$

n = the number of observations

x = the individual observation in one time period

y = the observation in the following time period of the same individual

x_i = the series of individual observations from 1 to n

m = the arithmetic mean of the observations

m_d = the arithmetic mean of differences $x - y$ in the sample

μ_d = the arithmetic mean in the population of $x - y$

S_d = standard deviation of the sample of the difference $x - y$

m_x = the arithmetic mean of the sample for the variable x

m_y = the arithmetic mean of the sample for the variable y

μ_x = the arithmetic mean of the population for the variable x

μ_y = the arithmetic mean of the population for the variable y

n_x = the number of observations in the sample for the variable x

n_y = the number of observations in the sample for the variable y

S_x = standard deviation of the sample for the variable x

S_y = standard deviation of the sample for the variable y

S = the weighed standard deviation of the samples for the variables x and y

t = t distribution according to Student

F = F distribution (Dixon & Massey 1957)

T = the rank sum according to Wilcoxon's test (— —)

U = value in the U test according to Mann-Whitney (— —)

p = probability level

Method for change of gas tensions

With the aim of analysing the effects on growth in length during change in oxygen and carbon dioxide tensions a method was preferred which was not immobilizing and not traumatic to the bone and simple enough for the long series necessary. The most convenient seemed to be to house the animals for a defined period in chambers where they could breathe the gases to be tested.

When the animals were to be exposed to the different breathing gases they were placed in either of two boxes one for the gas to be tested and one for the air as control. Five to ten animals could be housed in each of the boxes measuring $60 \times 35 \times 35$ cm. The litters were divided between the boxes as listed in the tables of the following chapters. The gases were supplied to the boxes through rubber tubes from standard gas cylinders. The gas cylinders were delivered by Syrgas AB Alfax Malmö Sweden with the gases purified for medical use. The gas mixtures were made with an accuracy of ± 0.3 per cent and tested by the manufacturer (Orsat — analysis). On three occasions as an additional control it was also checked at the Laboratory of Aviation and Naval Medicine Institute of Physiology. In a Scholander apparatus the deviations from the ordered concentrations were not more than 0.1–0.2 per cent. This department also delivered the cylinders with compressed air for the controls. At the Pressure Chamber Laboratory of this institute the gas exposures were also carried out. The boxes housing the animals were placed in the hyper- or hypobaric chamber where the desired pressure was reached in a couple of minutes. Thus there were two methods of changing the gas tensions: that is by change in gas concentrations of the cylinders and by variation in the barometric pressure of the chambers. The gas cylinders had a volume of 40 or 50 liters and a starting pressure between 150 and 200 kp/cm². By calculating the volume and the change in pressure it was possible to estimate the flow from the cylinders to the boxes. The flow was controlled by means of an orifice through which gas was supplied at adjustable feeding pressure from the reducing valve (Aga, Sweden) on the cylinder. This flow had been calibrated with a Douglas bag in the pressure chamber at the actual working pressures (manometers NAF Sweden) and the volume was later measured in a standard wet gas meter outside the chamber. These precautions about the flow rate of gases were taken because it was necessary to use a flow rate big enough to wash out the carbon dioxide produced by the animals during the 8 hrs of treatment. The flow was let out of the boxes after passage through holes in the lid. The ventilation needed was calculated to be 400 liters/kg bodyweight of animals per hour as follows. The maximal CO concentration which could be tolerated as harmless was supposed to be equivalent to 0.5 per cent at 1 atm abs. i.e. 0.25 per cent at 2 atm abs. The production of CO₂ is not more than equal to the consumption of oxygen, that is about 0.8 liters/kg/hr (Dittmer & Grebe 1958). This was rounded to

10 liter/kg/hr at 1 atm abs. If the CO_2 production was 10 liter/kg/hr and 0.25 per cent could be tolerated the flow must be 400 liters/kg/hr, i.e. 6.7 liters/min per kg of animal. The actual flow used was between 400 and 800 liters/kg/hr checked continuously as mentioned above. On two occasions it was also checked by Scholander analysis of the gas leaving the boxes. The calculations were verified. This flow through the boxes also gave a homogenisation of gases within the boxes further made certain by an extra increase in flow at the beginning of each exposure. Finally the flow prevented an increase of the temperature of the boxes because of the gas temperature decrease during the gas expansion. The temperature was occasionally recorded and found to be between 20 and 26°C within the boxes. The humidity of the air from the cylinders was close to 0 but the animals were given water freely in an open cup. Temperature, humidity, light, draught and noise were equal in the test and control hutches. The lids of the hutches were transparent allowing free inspection through the windows of the pressure chamber. Further details on concentrations and pressures of the tested gases are given in the chapters on results.

Periods of time for change in gas tensions and for measuring of growth

The oxygen exposures should be short enough to avoid the oxygen toxicity, which is proportional both to the time and the partial pressure (Bean 1945). At the same time the exposures had to be long enough to allow an accurate calculation of the growth in length. The method chosen allows labelling with 12 hrs intervals (Persson 1968). Shorter intervals seem to lead to increased difficulties in separation of the line frontiers in the microscopic sections. Thus the periods of growth labelling should not be shorter than 12 hrs but to allow sufficient time for transport of the animals to and from the place of treatment and time for the intravenous injections as well 8 hrs of treatment was considered to be convenient. A longer time would have limited the possible pressure of oxygen used because of toxicity. This toxicity is of two major types. One acute form of toxicity affects the central nervous system (Bert 1878) and is seen at higher tensions of oxygen that is about 3 atm abs and more. The second type is the pulmonary toxicity (Smith 1899) which can be elicited at oxygen pressures over 0.6 atm abs during extended treatments (Barach 1926). With increasing partial pressures of oxygen the time for this lung damage to evolve is progressively decreased. These problems are well known in humans and experimental animals (Bean 1945, 1964; Gerschman et al 1964) and hold for the rabbit as well (Binger et al 1927). This reduces the possible advantage of using longer periods of exposure and consequently it was decided in this investigation

to use a time of treatment of 8 hrs. Treatment given in intervals for instance of 2+2+2 hrs as in clinical praxis, reduces toxicity but has the disadvantage of masking effects in case of biphasic responses (Perison 1967) and was therefore not used in this investigation. The treatment was used only once in each animal because a repetition for several days would have led to another two important drawbacks: that is acclimatisation effects or haematopoiesis (Alland & Highman 1952; Brooksby et al 1966) and secondly it would have reduced the possibilities of analysing the time lags between the treatments and the changes in growth rate.

The relation between the time periods and the 8 hrs of treatment used in this investigation is illustrated in Fig. 2 and Fig. 3 for the 24 and the 12 hrs systems used respectively. As mentioned earlier only three consecutive periods of growth were measured in each animal. The maturing time of the cartilage cells from the layer of the reserve cells to the layer of degenerating and calcifying cells has been determined to be 2-4 days (Meisner & Leblond 1960; Kemner 1960) and it was evidently necessary to observe the possible effects on growth for 4-5 days after the treatment. This problem was solved by using three consecutive series of animals, overlapping each other with one day for the coupling together making possible analysis of changes in growth for an extended time. This is also illustrated in Fig. 2. Figures 2 and 3 also illustrate that the gas treatment was given almost until the end of the period 0. The time lag between the end of treatment and the following injection for tetracycline labelling of growth was less than 1 hr in series with 24 hrs periods and half an hour in series with 12 hrs periods. The reason for this was that there could be expected to be some withdrawal effects after the treatments. In this way it was possible to localize immediate effects and immediate withdrawal effects on different sides of the labelling lines and they were not allowed to compensate.

Figure 2

each other within the same period in case of diphasic effects on the growth rate (Persson 1967). The reasons given in this text for not using more than 8 hrs of treatment do not apply to later testing of decreased oxygen and increased carbon dioxide tensions, as the toxicity factors are not at all the same. Anyhow it was decided to use the same system of periods to allow for better possibilities for comparisons of the sensitivity of growth to the different test gases tried.

It was considered to be unimportant at which time in the day the injections were given as long as it was at the same time each day. For practical reasons they were given between 16.30 and 17.00 with the numbered animals in a constant order. The ordinary time for injection was less than one minute for each animal and each litter was begun with at a constant time each day, making the time factor equal in tests and controls. This holds for the entire material where periods of 24 hrs were used. When periods of 12 hrs were used the treatment was started at 11.00 and ended at 19.00 and the injections were given before 19.30 thereby marking the end of period 0. On the next morning the last injection of tetracycline was given before 07.30 that is after another 12 hrs exactly for each animal again with the animals in a constant order. In this case the time chosen for injection could be of some importance if there were a diurnal variation in growth rate, as suggested by Simmons & Nichols (1966). This possibility has been separately studied (Persson 1968) but no significant variation was found. However as long as the investigation is carried out as a comparison between tests and controls this possible factor is equalized.

Physical and Physiological data

As a background to the description of the results obtained some basic data from respiratory physiology will be recapitulated. Air contains 20.95 vol per cent of oxygen, 79.02 vol per cent of nitrogen and 0.03 vol per cent of carbon dioxide.

(Dittmer & Grebe 1958) The percentage of nitrogen given includes 0.95 vol per cent of inert gases. At a barometric pressure of 760 mm Hg in dry air this means an oxygen partial pressure of 158 mm Hg. Inspired into the alveoli the gas tension of oxygen has been reduced to just a little above 100 mm Hg because of the occurrence of water vapor and carbon dioxide being about 47 and 40 mm Hg respectively. From the alveolar air oxygen diffuses readily over to blood. In the capillary blood of the lungs pO_2 is close to the alveolar gas tension but it will be reduced by venous admixture corresponding to the ventilation/perfusion ratio and the resulting arterial oxygen tension is about 94 mm Hg. In the peripheral capillary beds this oxygen tension is reduced to 40 mm Hg in the venous blood returning to the lungs. In blood oxygen is carried in two ways i.e. combined with haemoglobin and in physical solution. The special affinity of oxygen for haemoglobin makes the arterial saturation to be about 97 per cent at the normal pO_2 of 94 mm Hg. Each gram of haemoglobin can combine with 1.34 ml of oxygen and if the normal haemoglobin content is 15 g per cent this means that the haemoglobin in blood carries about 20 ml of oxygen per 100 ml blood under normal circumstances. Meanwhile the amount of oxygen in physical solution is about 0.3 ml/100 ml. As this physical solution has a linear relation to the gas tension in the gaseous phase it means that giving 100 per cent of oxygen in the respiratory air the pO_2 in the arterial blood will be about 673 mm Hg increasing the oxygen content by 2.2 vol per cent of which 1.7 vol per cent is in physical solution (Linehan 1964). This means that an increase in tension of oxygen by 6.7 times increases the carrying capacity about 11 per cent. This moderate increase in capacity is however combined with a considerable increase in the diffusion pressure. The cited figures hold approximately for the rabbit as well (Chapter 7).

When the environmental barometric pressure is changed by means of a pressure chamber (Chapter 3) the gas tension of oxygen will be altered simultaneously. If the pressure is raised to 2 atm abs. (atm abs. = atmospheres absolute = 760 mm Hg) that is 1520 mm Hg the oxygen tension in air will be about 304 mm Hg. If the animals are breathing pure and dry oxygen at the same pressure the oxygen partial pressure will be 1520 mm Hg and the oxygen content in the blood will be increased from about 20 ml/100 ml to about 25.2 ml/100 ml.

In Chapter 4 the results will be given of decreased oxygen tensions by the means of a hypobaric chamber that is a pressure tank where the barometric pressure can be reduced by vacuum pumps. The same principles applies to this that is for instance if the pressure is reduced to half that is from 760 to 380 mm Hg the oxygen partial pressure will be reduced from 158 to 79 mm Hg if there is no water vapor. At 6000 meters altitude the barometric pressure is about 354 mm Hg the oxygen partial pressure about 76 mm Hg and the alveolar oxygen tension about 35 mm Hg the alveolar carbon dioxide tension finally

Physical and Physiological data

As a background to the description of the results obtained some basic data from respiratory physiology will be recapitulated. Air contains 20.9% vol per cent of oxygen, 79.02% vol per cent of nitrogen and 0.03% vol per cent of carbon dioxide.

(Dittmer & Grebe 1958) The percentage of nitrogen given includes 0.93 vol per cent of inert gases. At a barometric pressure of 760 mm Hg in dry air this means an oxygen partial pressure of 158 mm Hg. Inspired into the alveoli the gas tension of oxygen has been reduced to just a little above 100 mm Hg because of the occurrence of water vapor and carbon dioxide being about 47 and 40 mm Hg respectively. From the alveolar air oxygen diffuses readily over to blood. In the capillary blood of the lungs pO_2 is close to the alveolar gas tension but it will be reduced by venous admixture corresponding to the ventilation/perfusion ratio and the resulting arterial oxygen tension is about 94 mm Hg. In the peripheral capillary beds this oxygen tension is reduced to 40 mm Hg in the venous blood returning to the lungs. In blood oxygen is carried in two ways i.e. combined with haemoglobin and in physical solution. The special affinity of oxygen for haemoglobin makes the arterial saturation to be about 97 per cent at the normal pO_2 of 94 mm Hg. Each gram of haemoglobin can combine with 1.34 ml of oxygen and if the normal haemoglobin content is 15 g per cent this means that the haemoglobin in blood carries about 20 ml of oxygen per 100 ml blood under normal circumstances. Meanwhile the amount of oxygen in physical solution is about 0.3 ml/100 ml. As this physical solution has a linear relation to the gas tension in the gaseous phase it means that giving 100 per cent of oxygen in the respiratory air the pO_2 in the arterial blood will be about 673 mm Hg increasing the oxygen content by 2.2 vol per cent of which 1.7 vol per cent is in physical solution (Linthan 1964). This means that an increase in tension of oxygen by 6.7 times increases the carrying capacity about 11 per cent. This moderate increase in capacity is however combined with a considerable increase in the diffusion pressure. The cited figures hold approximately for the rabbit as well (Chapter 7).

When the environmental barometric pressure is changed by means of a pressure chamber (Chapter 3) the gas tension of oxygen will be altered simultaneously. If the pressure is raised to 2 atm abs (atm abs = atmospheres absolute = 760 mm Hg) that is 1520 mm Hg the oxygen tension in air will be about 304 mm Hg. If the animals are breathing pure and dry oxygen at the same pressure the oxygen partial pressure will be 1520 mm Hg and the oxygen content in the blood will be increased from about 20 ml/100 ml to about 22 ml/100 ml.

In Chapter 4 the results will be given of decreased oxygen tensions by the means of a hypobaric chamber that is a pressure tank where the barometric pressure can be reduced by vacuum pumps. The same principles apply to this that is for instance if the pressure is reduced to half that is from 760 to 380 mm Hg the oxygen partial pressure will be reduced from 158 to 79 mm Hg if there is no water vapor. At 6000 meters altitude the barometric pressure is about 354 mm Hg the oxygen partial pressure about 76 mm Hg and the alveolar oxygen tension about 35 mm Hg the alveolar carbon dioxide tension finally

is about 30 mm Hg, compared to 40 at sea level (*Luft* 1961). This oxygen tension corresponds to an oxygen saturation of the haemoglobin of about 68 per cent, which means that the oxygen carrying capacity per 100 ml of blood has been reduced from 20 to about 13.6 vol per cent. The oxygen lack causes a hyperventilation, which reduces the alveolar carbon dioxide tension. At 5000 meters the alveolar oxygen tension still according to *Luft* (1961), is about 42 mm Hg, at 4000 meters it is about 51 mm Hg, at 3000 meters it is about 62 mm Hg and the alveolar carbon dioxide tension is then about 36 mm Hg.

In Chapter 6 the investigation of increased carbon dioxide tension in air will be described. When the normal carbon dioxide tension is raised from about 0.04 vol per cent to 3 vol per cent the alveolar carbon dioxide tension increases from about 45.5 to 47.5 mm Hg. At 5 vol per cent of carbon dioxide in air the alveolar tension is about 49.5 mm Hg, and at 7 vol per cent finally, the alveolar carbon dioxide tension is about 58 mm Hg in humans (*Barcroft & Margaria* 1931, *Patterson et al* 1955). At this carbon dioxide tension the ventilation rate had increased from about 12 to about 80 liters/min and it was about the highest carbon dioxide tension that could be tolerated by the healthy test subjects. After 18 hrs in about 4 per cent carbon dioxide in air the ventilation is still about 200 per cent of the normal (*Dittmer & Grebe* 1958). After 15–20 min of 3.5 per cent carbon dioxide breathing in 16 humans the jugular venous pH in blood had decreased from a mean of 7.35 to 7.32 and the arterial pH had decreased from 7.39 to 7.35 (*Patterson et al* 1955).

After this short presentation of some basic figures, illustrating important principles from the respiratory physiology the results obtained by testing the effects on longitudinal bone growth from short time alterations of respiratory gases as specified later, will be described.

RESULTS OF INCREASED OXYGEN TENSIONS

The preliminary studies of the effects on growth during increased respiratory oxygen tension for 2+2+2 hrs with 100 per cent oxygen at 2 atm abs during one day earlier referred to had indicated an increased growth in length during the exposure followed by a depression the day after. On the basis of these results the following questions were considered for further studies

Does omitting of the pauses in the intermittent oxygen exposure disclose a growth acceleration of significant magnitude earlier hidden by a diphasic effect between the periods of hyperoxygenation and the pauses between?

Does an observation extended in time after the oxygen exposure reveal later effects which can be related to younger maturing stages of the cartilage cells which may not reach the calcification zone until after a couple of days?

Does there exist a dose response relationship between effects on growth and the oxygen tension used during the 8 hrs of treatment?

This part of the investigation comprises a total of 193 rabbits 102 treated with increased tensions of oxygen and 91 litter mates treated simultaneously with air for control. The oxygen when said to be 100 per cent pure contained less than 0.5 per cent inert gases which can be ignored. They are a part of the air also and they have no proved biological function. The results are given under four headings below named A—D. The percentage of oxygen in the gas mixtures conducted through the boxes, is specified and the ambient pressure is given in atm abs. The pressure specified means the normal ambient pressure for the day of the experiment and under A another 1 atm abs achieved by raising the pressure this amount in the hyperbaric chamber where the boxes were stationed. The barometric pressure on the days of treatment varied only between 745—770 mm Hg which was not compensated for. During the 8 hrs of hyperbaric oxygenation under A, the pressure in the chamber was allowed to vary ± 0.1 atm abs at most, which means ± 5 per cent.

is about 30 mm Hg compared to 40 at sea level (Luft 1961) This oxygen tension corresponds to an oxygen saturation of the haemoglobin of about 68 per cent, which means that the oxygen carrying capacity per 100 ml of blood has been reduced from 20 to about 13.6 vol per cent The oxygen lack causes a hyperventilation which reduces the alveolar carbon dioxide tension At 5000 meters the alveolar oxygen tension still according to Luft (1961) is about 42 mm Hg, at 4000 meters it is about 51 mm Hg, at 3000 meters it is about 62 mm Hg and the alveolar carbon dioxide tension is then about 36 mm Hg

In Chapter 6 the investigation of increased carbon dioxide tension in air will be described When the normal carbon dioxide tension is raised from about 0.04 vol per cent to 3 vol per cent, the alveolar carbon dioxide tension increases from about 45.5 to 47.5 mm Hg At 5 vol per cent of carbon dioxide in air the alveolar tension is about 49.5 mm Hg and at 7 vol per cent finally, the alveolar carbon dioxide tension is about 58 mm Hg in humans (Barcroft & Margaria 1931, Patterson et al 1955) At this carbon dioxide tension the ventilation rate had increased from about 12 to about 80 liters/min and it was about the highest carbon dioxide tension that could be tolerated by the healthy test subjects After 18 hrs in about 4 per cent carbon dioxide in air the ventilation is still about 200 per cent of the normal (Dittmer & Grebe 1958) After 15–20 min of 3.5 per cent carbon dioxide breathing in 16 humans the jugular venous pH in blood had decreased from a mean of 7.35 to 7.32 and the arterial pH had decreased from 7.39 to 7.35 (Patterson et al 1955)

After this short presentation of some basic figures illustrating important principles from the respiratory physiology the results obtained by testing the effects on longitudinal bone growth from short time alterations of respiratory gases as specified later will be described

A 80 and 100 per cent oxygen at 2 atm abs with growth recording periods of 12 hrs

This experimental series was intended to answer the first question if omitting of the treatment pauses earlier tried, would disclose a significant change in growth, hitherto covered as being *diphasic* within the growth period measured. Pure oxygen at 2 atm abs was first tried, but turned out to be over the limit of toxicity for the treatment of 8 hrs used. Therefore 80 per cent oxygen was tried for the same time and the same pressure that is an oxygen pressure of 1.6 atm abs. In the first group 2 animals out of 7 died of respiratory failure soon after the end of exposure, and in the second group 2 of 13 died with the same symptoms. In both cases it was animals in the same litter that reacted in this way and another 5 animals (not excluded) in these two litters showed symptoms of respiratory distress but survived the measuring period. The post mortem examination of the lungs disclosed macroscopic hepatisation, i.e. alveolar exudation blood engorgement and haemorrhages as described by Lorrain Smith (1899) in 11 out of 18 rabbits treated with 80 or 100 per cent oxygen for 8 hrs. In three of the cases the changes were slight as also in one of the controls. Microscopic examination was not made as these changes have been thoroughly studied (Smith 1899). As toxicity reactions occurred in both groups it was considered to be justified to add them together for the statistical evaluation. The arithmetic mean of the changes seemed to be the same as well and the figures are given in Table 2 and 3. The effects on growth is illustrated in Fig. 4 as alteration of mean differences between consecutive time periods. The mean values given in Tables 2—3 show an increase in growth during period 0 of 4 per cent in the oxygen group compared to 2 per cent in the control and a decrease during period $+1/2$ of 12 per cent in the oxygen group compared to 3 per cent in the control. The statistical comparison between changes in test and control eliminates the significance of the stimulation observed during hyperoxygenation ($-1/ \rightarrow 0$ $r=1.35^-$) but shows a significant decrease in growth for the oxygen group during the 12 hrs after the treatment ($0 \rightarrow +1/2$ $U=2.60^{**}$). Because of the toxicity reactions observed these exposures were not continued. The changes observed are illustrated in Fig. 4.

As the sensitivity of the measuring method was not expected to allow shorter observations it was necessary to lower the partial pressure of oxygen used and 100 per cent at 1 atm abs was therefore chosen being simpler to handle than 80 per cent oxygen at 2 atm abs.

B 100 per cent oxygen at 1 atm abs with growth recording periods of 12 hrs

This part describes the immediate effects up to 12 hrs after the end of the exposure to 100 per cent oxygen at 1 atm abs. No animals died or developed respiratory distress. Only one animal showed traces of the pulmonary hepatisation observed in A. Consequently this partial pressure of oxygen is about the highest tolerable for 8 hrs in young rabbits. Individual values and mean values of growth rates are given in Tables 4 and 5. The changes are further illustrated in Fig. 5 as mean differences in test and control. The mean values given in Tables 4 and 5 show an increase in growth during period 0 of 5 per cent in test compared to 0 per cent in control and a decrease in growth during period $+1/2$ of 11 per cent in test compared to 7 per cent in control. Statistically the first change is significant ($t=2.86^{**}$) the second is insignificant ($t=1.56^{-}$).

This part B had given a determination of the highest tolerable doses of oxygen for 8 hrs and shown that the increase in growth earlier not significant was statistically reliable. It was now necessary to illuminate on the second question whether an observation of growth extended in time after the therapy would disclose further changes referable to different stages of the cartilage cell development. This demanded an observation time of 5 days (Messier and Leblond 1960) after the exposure with a hyperoxygenation of 100 per cent at 1 atm abs as determined to be the highest dose which could be tolerated.

C 100 per cent oxygen at 1 atm abs with growth recording periods of 24 hrs

With the partial pressure of oxygen and time of exposure identical with that in part B it was considered to be justified for this prolonged observation to change the growth recording periods from 12 to 24 hrs as the earlier effects were already determined. This would allow an easier handling in respect of time consumption and give a reduced relative error of measurements which was supposed to outweigh the possible advantage of using 12 hrs as the period for the study. For changes in growth occurring later in time than 12 hrs after the gas exposure it could be presumed to be a reaction flattened out in time, thereby making it sufficient to extend the periods in use to 24 hrs. In the preliminary investigation (Persson 1967) the 24 hrs period had also been used.

The test groups were given 100 per cent of oxygen at 1 atm abs for 8 hrs during period 0 the controls simultaneously exposed to air from gas cylinders.

The results are given in Tables 6 and 7 showing in comparison a significant increase of 3 per cent between period -1 and period 0 ($t=3.42^{**}$). The continued observation for 5 periods of 24 hrs after period 0 did not reveal any statistically significant alteration in the continued growth rate of the metaphysis with comparison between test and control ($0 \rightarrow +1$ $t=0.23$ $+1 \rightarrow +2$ $t=0.19$ $+2 \rightarrow +3$ $t=0.04$ $+3 \rightarrow +4$ $t=1.24$ $+4 \rightarrow +5$ $t=0.89$). This is illustrated in Fig 6. This does not however indicate that the growth in test and control was the same after the end of the oxygen treatment. From the statistical point of view on the contrary it means that the acceleration of growth observed during the treatment with 100 per cent of oxygen continued as a growth rate on a little higher level than in the control group. It might be that the growth stimulation subsided slowly and extended over several periods after the treatment making each step so small that the method did not allow measuring of the changes. The recorded stimulation was 3 per cent and the error of the method is 1-2 per cent (Hansson 1967 Persson 1967) which makes this possibility probable. To evaluate this and to answer the question as to when the stimulation ends the absolute values of growth were compared. This is made in Fig 7 as a quotation of the mean value of growth in the test with that in the control group for the same day. The growth in the test group is thereby expressed as a percentage of the control for each day. In this way the overlapping groups in period +1 and +3 respectively were utilized by summing which makes the samples larger on these two days. This comparison indicated that the stimulation subsided from +4 per cent to 1 per cent from period +2 to +4 (Fig 7).

Figure 6

Longitudinal growth of the proximal tibial metaphysis in rabbits at increased oxygen tension by exposure to 100% of oxygen at 1 atm abs for 8 hrs during period 0. Growth recordings by oxytetracycline labelling for 7 consecutive time periods of 24 hrs. Mean growth changes in microns from day to day measured within the same animal. Figures made continuous by overlapping observations in period +1 and +3.

Figure 7

Per cent growth in length from the proximal tibial growth plate of rabbits treated with 100 % O_2 at 1 atm abs for 8 hrs during period 0 compared to control groups of littermates simultaneously treated with air from gas cylinders

As the gases tried might influence the respiration and because of the fact that rabbits regulate their heat by panting instead of sweating some attention had to be paid to the *temperature factor*. In testing 100 per cent of oxygen at 1 atm abs for 8 hrs the rectal temperatures were measured with a mercury thermometer in 14 animals before and within a minute after the exposure. They ranged between 38.0 and $39.5^{\circ}C$ but there was no difference between tests and controls. This is in accordance with Valenzuela (1877). The temperature of the two boxes was also the same at the end of the experiment.

D 100 to 21 per cent oxygen at 1 atm abs with growth recording periods of 12 hrs

A preliminary test of 80 per cent and 40 per cent of oxygen in nitrogen for 8 hrs at 1 atm abs was made in 25 animals but the effects were insignificant. It was therefore considered not worth carrying on with to avoid a further splitting up of the material. These values are therefore not reported in detail and

an analysis of these pressures has not been carried out because a determination of the limits of the effects was not essential for this investigation

Regarding the questions in the beginning of this chapter the following statements can be made. The omitting of the intervals of the hyperbaric oxygenation earlier reported did show an influence by increased oxygen on the longitudinal growth of the metaphysis which was statistically significant. An acceleration of growth starting during exposure to 100 per cent of oxygen at 1 atm abs was observed. Further an extended observation for 5 days after the exposure did not reveal statistically significant changes but probably a gradual decrease in growth back to the level of the control groups during periods +3 and +4 occurred (Fig. 7). A dose response relationship existed so that toxicity reactions occurred when the partial pressure of oxygen was increased above 1 atm abs for 8 hrs eliminating the stimulation.

After the examination of effects on growth caused by increased oxygen tensions of the respiratory air it seemed to be valuable for the interpretation to study as well the effects of reduced oxygen tensions.

Figure 7

Air at 3000 meters altitude with growth recording periods of 12 hrs

The experimental results are given in Table 8 to 1e compared with the control result in Table 9. There was no significant effect on growth at 3000 meters (970 mmals) for the 8 hrs of exposure used. The comparison values statistically were $-1/2 \rightarrow 0$ is 0.90~ and $0 \rightarrow +1/2$ is 0.04~

RESULTS OF DECREASED OXYGEN TENSIONS

The simplest way to reduce the oxygen tension for groups of animals during 8 hrs seemed to be by using a hypobaric chamber. It was considered indicated to begin with this method, although a lowering of the environmental pressure would reduce the partial pressure of other gases in air as well. These other gases were not expected to influence the growth rates. The control animals were housed outside the chamber and the test animals inside the chamber kept in an open box. Pellets and water were given freely to both as always. The pressure in the chamber was lowered to pressures corresponding to 3000, 4000, 5000 and 6000 meters respectively in four series. Exposure and measuring times were as described in Chapter 2 (Fig. 2 and 3). According to the transformation list of the station 3000 meters was equivalent to 526 mm Hg, 4000 meters was 462 mm Hg, 5000 meters was 405 mm Hg and 6000 meters was equivalent to 354 mm Hg. An adjustable spring loaded valve kept the pressure constant by letting in a small flow of air which increased if the pumps were about to lower the pressure too much. The hypobaric chamber was cylindrical, length 225 cm, diameter 254 cm and this magnitude made special efforts for temperature regulation and carbon dioxide control unnecessary. The results will be described in the order the experiments were performed, beginning with the moderate hypoxia accomplished by reducing the pressure to the equivalent of 3000 meters with growth recording in half days. Stepwise in different series the oxygen lack was increased in simulated altitudes from 3000 to 6000 meters and after the 12 hrs series of growth recordings the same degrees of hypoxia were analysed with growth recording periods of 24 hrs for a more extended observation time. This part of the investigation comprises 461 animals distributed as specified in the tables.

1. Air at 3000 meters altitude with growth recording periods of 12 hrs

The experimental results are given in Table 8 to be compared with the control result in Table 9. There was no significant effect on growth at 3000 meters (0.70 atm abs) for the 8 hrs of exposure used. The comparison values statistically were $-1/2 \rightarrow 0$ $t=0.90$ and $0 \rightarrow +1/2$ $t=0.04$.

B Air at 4000 meters altitude with growth recording period of 12 hrs

The influences on growth at 4000 meters (0.61 atm abs) are given in Table 10 to be compared with the control values in Table 9. There is an almost significant decrease in growth in comparison between the period before the treatment and the period of treatment and this significance is unaltered in comparison with the control group ($-1/2 \rightarrow 0$ $t=2.57^*$ $0 \rightarrow +1/2$ $t=0.51$)

D Air at 6000 meters altitude with growth recording periods of 12 hrs

The results of testing growth at a simulated altitude of 6000 meters (0.47 atm abs) are given in Table 12 to be compared with the control values in Table 9. There is a decrease in mean growth of 7 per cent in comparison between the day before and the day of treatment and a further decrease of another 5 per cent to the day after. The first decrease is highly significant also compared to the controls ($-1/2 \rightarrow 0$ $t = -4.52^{***}$ $0 \rightarrow +1/2$ $t = 0.96$).

C Air at 5000 meters altitude with growth recording periods of 12 hrs

The results of testing growth at 5000 meters (0.54 atm abs) are given in Table 11 to be compared with the control animals in Table 9. The differences are statistically insignificant ($-1/ \rightarrow 0$ $t=1.13$, $0 \rightarrow +1/$ $t=1.72$) in comparison between test and control animals but significant within the test group (Table 11). The direction of the changes in growth is the same as at 4000 meters.

This part of the investigation (A—D) had shown that there was a decreased growth in length during air breathing at reduced barometric pressure, persisting during the first 12 hrs after the exposure. The changes are highly significant only at 6000 meters altitude. The next step was to follow these effects for an extended period after the treatment. On the same grounds as given in Chapter 6 measuring periods of 24 hrs were used for the continued study. This is given below (E—H).

E Air at 3000 meters altitude with growth recording periods of 24 hrs

The results of these exposures to air at 3000 meters (0.70 atm abs) for 8 hrs are given in Table 13 to be compared to the controls in Table 14. There are no significant effect at this comparison even during this extended observation for 5 days after the end of treatment.

F Air at 4000 meters altitude with growth recording periods of 24 hrs

The results of studying growth during air breathing at 4000 meters (0.61 atm abs) for 8 hrs are given in Table 15 to be compared to the control values in

Figure 8

Longitudinal growth of the proximal tibial metaphysis in rabbits at reduced oxygen tension by exposure to simulated altitudes of 3000 4000 5000 and 6000 meters for 8 hrs during period 0. Growth recordings by oxytetracycline labelling for 7 consecutive time periods of 24 hrs. Mean growth changes in microns from day to day measured within the same animal. Figures made continuous by overlapping observations in period +1 and +3.

Table 14 This comparison shows a highly significant decrease in growth from the day of exposure to the day after ($t=5.97^{***}$) and further by a return towards normal as a highly significant increase between period +1 and +2 ($t=4.61^{***}$). The first decrease is about 11 per cent the following increase about 5 per cent between periods +1 and +2. There is a further increase of 2 per cent between periods +2 and +3 ($t=1.92$). The effects are illustrated in Fig 8. After period +3 there are no significant changes (+3 \rightarrow +4 $t=0.13$ +4 \rightarrow +5 $t=1.01$).

Figures made continuous by overlapping observations in period +1 and +3.

and period +1 there was a highly significant decrease ($U=4.08^{***}$) measuring 11 per cent in mean value. After this there was a highly significant increase in growth ($U=4.48^{***}$) between period +1 and period +2 measuring 6 per cent. The following days showed no significant changes between consecutive days in the test group but in the control group there was a significant decrease in growth of unknown cause during the last day (Table 14).

H Air at 6000 meters altitude with growth recording periods of 24 hrs

The results of studying growth at 6000 meters (0.47 atm abs) for 8 hrs are given in Table 17 with controls in Table 14. At this altitude a comparison of the groups showed a highly significant decrease in growth already between period -1 and the period of exposure (0) measuring 9 per cent ($T=33.5^{***}$). The earlier observed decrease given in part D is verified and followed by a further decrease the day after treatment of another 20 per cent now highly significant ($T=23.5^{***}$). The increase between period +1 and +2 observed at 4000 and 5000 meters is still significant at 6000 meters ($U=2.92^{**}$) in spite of the pronounced reduction observed during the first two periods at this altitude. During period +2 and until +5 there is still no significant delayed change in growth in comparison between tests and controls (+2 \rightarrow +3 $U=0.43$ +3 \rightarrow +4 $t=2.02$ +4 \rightarrow +5 $t=0.05$). Many animals seemed to regain a normal growth during these days (Table 17) but the mean change does not fully compensate for the decreased growth in the first days (Fig. 8).

As pronounced effects had been observed at the altitudes studied it was considered to be of no value to proceed further as the hypoxia if further increased would severely influence on the general condition of the animals which was not the intention. The growth reactions described in A-H were caused by reduced barometric pressure and it was considered necessary to investigate if the same changes could be induced by a reduction of the oxygen concentration alone at a normal barometric pressure. This was necessary not only to exclude other factors of the hypobaric condition used which might influence on growth but also to prepare the way for the investigation of the importance of the carbon dioxide pressure because reduction of the oxygen tension induces a hyperventilation which gives a hypocapnia. The first step was to try 15 per cent of oxygen at normal pressure corresponding to about 4500 meters of altitude in air breathing.

G Air at 5000 meters altitude with growth recording periods of 24 hrs

This study of the effects on growth at exposure to 5000 meters (0.54 atm abs) for 8 hrs is described in Table 16, with the control animals listed in Table 14. A comparison between the two materials showed no immediate effect at exposure ($-1 \rightarrow 0$ $t=1.50$) but with comparison of changes between period 0

Table 16

The following days showed no significant changes between consecutive days in the test group but in the control group there was a significant decrease in growth of unknown cause during the last day (Table 14).

H Air at 6000 meters altitude with growth recording periods of 24 hrs

The results of studying growth at 6000 meters (0.47 atm abs) for 8 hrs are given in Table 17 with controls in Table 14. At this altitude a comparison of the groups showed a highly significant decrease in growth already between period -1 and the period of exposure (0) measuring 9 per cent ($T=13.5^{***}$). The earlier observed decrease given in part D is verified and followed by a further decrease the day after treatment of another 20 per cent now highly significant ($T=23.5^{**}$). The increase between period +1 and +2 observed at 4000 and 5000 meters is still significant at 6000 meters ($U=2.92^{**}$) in spite of the pronounced reduction observed during the first two periods at this altitude. During period +2 and until +5 there is still no significant delayed change in growth in comparison between tests and controls (+2 \rightarrow +3 $U=0.43$ - +3 \rightarrow +4 $t=2.02$ - +4 \rightarrow +5 $t=0.05$). Many animals seemed to regain a normal growth during these days (Table 17) but the mean change does not fully compensate for the decreased growth in the first days (Fig. 8).

As pronounced effects had been observed at the altitudes studied it was considered to be of no value to proceed further as the hypoxia if further increased would severely influence on the general condition of the animals which was not the intention. The growth reactions described in A-H were caused by reduced barometric pressure and it was considered necessary to investigate if the same changes could be induced by a reduction of the oxygen concentration alone at a normal barometric pressure. This was necessary not only to exclude other factors of the hypobaric condition used which might influence on growth but also to prepare the way for the investigation of the importance of the carbon dioxide pressure because reduction of the oxygen tension induces a hyperventilation which gives a hypocapnia. The first step was to mix 1 per cent of oxygen at normal pressure corresponding to about 4500 meters of altitude in air breathing.

I Twelve per cent oxygen in nitrogen at 1 atm abs with growth recording periods of 24 hrs

Twelve per cent oxygen corresponds to about 4500 meters altitude that is a barometric pressure of 434 mm Hg. The exposure was for a duration of 8 hrs during period 0. The results are given in Table 18 with the control animals in Table 19. The statistical comparison between changes in tests and controls shows a significant decrease in growth (-6 per cent) between the period of exposure and the day after ($U=2.93^{**}$). A subsequent increase reported in part F→H is observed (Table 18) but not statistically significant ($U=1.03^{-}$). The other comparisons between changes in tests and controls showed no differences either ($+1 \rightarrow +2$ $U=1.03^{-}$ $+2 \rightarrow +3$ $t=1.02^{-}$ $+3 \rightarrow +4$ $U=0.25^{-}$ $+4 \rightarrow +5$ $t=1.87^{-}$). It was considered to be indicated to further lower the oxygen tension.

K Ten per cent oxygen in nitrogen at 1 atm abs with growth recording periods of 24 hrs

Ten per cent oxygen corresponds to an altitude of about 5900 meters or a barometric pressure of 365 mm Hg. The exposure was for a duration of 8 hrs as always. Rabbits can survive even 8 or 7 per cent oxygen (Binger 1927) but

they can not keep a normal weight beyond 5500 meters (Champbell 1935) The results are given in Table 20 with the control animals in Table 21 The tendencies earlier described were again observed The relative changes in growth were -7 per cent during the day of exposure compared to the day before again -7 per cent between period 0 and period +1 there after +8 per cent to period +2 A comparison of the absolute values of growth during the following periods to +5 shows that the control animals in average have a little better growth rate than the test groups which illustrates that the changes at this degree of hypoxia probably are affecting the growth for an extended time after return to normal oxygen tension This was also the case at 6000 meters earlier described The statistical comparison between changes in tests and in controls demonstrates an almost significant decrease in growth from the day before to the day of treatment ($U=2.02^*$) and a further decrease to the day after treatment which was significant ($U=2.93^{**}$) After this time there was no statistical significance in the differences between changes in test and in control up to five days after the end of the exposure to 10 per cent of oxygen compared to air (+1 \rightarrow +2 $t=1.21$ +2 \rightarrow +3 $t=0.09$ +3 \rightarrow +4 $t=0.69$ +4 \rightarrow +5 $t=0.27$)

Figure 9

Longitudinal growth of the proximal tibial metaphysis in rabbits at reduced oxygen on by exposure to a gas mixture with 10 and 12 per cent of oxygen respectively in nitrogen at 1 atmosphere. Exposure time 8 hrs during period 0. Growth recordings by oxytetracycline label no 30 7 consecutive time periods of 7 days. Mean growth changes in microns found 7 days measured within the same animal. Figures made continuous by overlapping observations in period +1 and +3

Figure 10

Per cent growth in length from the proximal tibial growth plate of rabbits treated with 10 % O₂ in N₂ at 1 atm abs for 8 hrs during period 0 compared to control groups of litter mates simultaneously treated with air from gas cylinders

The decrease in growth during hypoxia is again observed for 24 hrs after the end of treatment (Fig 9). The increase that followed between period +1 and +2 is not statistically significant in the test of 12 and 10 per cent of oxygen reported above which it was at the test of growth during hypobaric conditions corresponding to 4000, 5000 and 6000 meters altitude. Looking at the absolute values of growth in the 10 per cent oxygen series however the same increase is observed during that time. This is illustrated in Fig 10 where test values have been divided by the control of the same day as described in Chapter 3 for 100 per cent oxygen (Fig 7).

Height of the cartilage plate after 10 per cent of oxygen for 8 hrs

It was clear that a lowering of the partial pressure of oxygen in the respiratory air did affect the growth in length of the metaphysis. This influence was in a certain proportion to the degree of hypoxia induced with no changes at 3000 meter and severe changes at 6000 meters altitude for 8 hrs in unacclimatized animals. The question was now whether this effect on the growth rate of the metaphysis represented a temporary shift of the calcification border or affected the total epiphyseal cartilage plate. Theoretically three different possibilities existed:

- 1 The hypoxia acted mainly in the zone of degeneration and calcification where the cartilage cells meet the blood vessels again
- 2 The hypoxia acted more evenly over all the maturing stages of the cartilage cells from the reserve layer to the degenerating layer
- 3 The hypoxia acted more in the top layers of proliferating cells than in the metaphyseal end

This question could possibly be answered by measuring of the thickness of the whole cartilage plate simultaneously with a recording of the metaphyseal growth rate by tetracycline labelling as above. The same three possibilities regarding the position of the most sensitive cells presumably existed also at increased doses of oxygen earlier described but as the effects on growth observed during hyperoxia were quantitatively smaller it was considered to be advisable to study this first at a reduced oxygen pressure.

If conditions agreed mostly to point one above there could be expected to be an increased height of the plate as the younger cells then should have continued the growth while the calcification border had slowed down during decreased oxygen tension as recorded at 10 per cent of oxygen in nitrogen described above in this chapter. This slow down was maximal in period +1 up to 24 hrs after the end of the exposure to 10 per cent of oxygen. This moment was therefore chosen for sacrificing 32 rabbits at the age generally used. Half of the series was treated in low oxygen half in air. The proximal tibia of one side was taken for fixation in formaline, decalcified, sectioned with a microtome and mounted. Standard staining with haematoxylin-eosin was used and the height of the cartilage plate was measured with the same optic equipment as elsewhere in this investigation. The readings were made blind with decodification of tests and controls after the reading. Efforts were made to measure on sections where the columns of the cells were longitudinally cut. The other tibia in each animal was taken for ultraviolet micro copy of the oxytetracycline labelling made simultaneously. The growth rates showed the decreases described. The statistical comparison of the height of the plate in tests and controls showed an almost significant difference, the height being less in animals exposed to 10 per cent of oxygen ($t=7.17^*$ 31 degrees of freedom). The differences were

CHAPTER 5

RESULTS OF DECREASED OXYGEN TENSION COMBINED WITH INCREASED CARBON DIOXIDE TENSION

A Ten per cent oxygen plus five per cent carbon dioxide in nitrogen at 1 atm abs with growth recording periods of 24 hrs

The reason for addition of carbon dioxide to the gas with reduced oxygen tension is given in the end of Chapter 4. It was natural to continue with 10 per cent of oxygen in nitrogen because of the pronounced effects on growth observed at that concentration of oxygen. The problem was to select the concentration of carbon dioxide to be added for preventing the outwashing of carbon dioxide during the hyperventilation which was induced by the oxygen lack in the experiments described in Chapter 4. It was decided to use 5 per cent carbon dioxide admixture to reach an approximately normal alveolar CO₂ tension. If this concentration would give a slight accumulation of carbon dioxide instead, this factor could be separately studied later. In this part of the investigation the same technic as described in Chapter 4 was used only with the difference that the gas cylinders contained 10 per cent oxygen plus 5 per cent carbon dioxide all in nitrogen. The treatment was for 8 hrs at 1 atm abs with growth recording periods of 24 hrs as earlier described.

The results are given in Table 23 with the control values in Table 24. The effects are further recorded in Fig. 11 as the mean differences between consecutive time periods in tests and controls separately. The mean growth in the test group showed a decrease of 4 per cent from the period before treatment to the period of treatment and a further decrease of 8 per cent to the period after exposure followed by an increase in growth of 8 per cent between period +1 and +2. After this time there was no statistical difference between the changes in test and control groups. The statistical comparison values were $-1 \rightarrow 0$ $U=3.68^{**}$ $0 \rightarrow +1$ $U=4.40^{***}$ $+1 \rightarrow +2$ $t=5.52^{***}$ $+2 \rightarrow +3$ $t=0.41$ $+3 \rightarrow +4$ $t=0$ $+4 \rightarrow +5$ $t=0.95$. The degrees of freedom can be seen in Table 23 and 24.

As in chapter 3 the temperature was measured to see whether the hyperventilation induced by this hypoxia had influenced on the body heat regulation. In all 15 rabbits with 7 controls and 8 test animals were used for this. In opposition to the increased and decreased oxygen exposures an effect was now measurable. At the end of the exposure to 5 per cent carbon dioxide plus 10 per

quantitatively small. This result implies that the effect was not solely localised to the degenerating layer of the cartilage plate but to a major part. Point three was excluded by the fact that decreases in growth were observed already during the exposure (Fig 9 and 10). If the height of the plate had been found to be unchanged by the hypoxia it had then been necessary to measure it immediately at the end of the exposure to rule out a possibility, that it had regained its thickness during the 24 hrs after exposure which now were allowed to pass. There is a parallelity between the metaphyseal growth and the height of the cartilage plate in less acute experiments (Hansson 1967) but to limit the present work it was not carried on further, and the other experiments performed were not supplemented by this method.

At this point it was necessary to consider the possibility that the changes observed were not directly due to the reduced oxygen tension but to a respiratory alkalosis with hypocapnia caused by the hyperventilation which was induced by the oxygen lack. This hyperventilation did not influence on the body temperature as measured immediately after the exposure to a simulated altitude of 5900 meters for 8 hrs. The rectal temperatures before and after treatment showed no differences between 7 treated animals and 5 controls. To prevent the out-washing of carbon dioxide during the hypoxemic hyperventilation thereby keeping $p\text{CO}_2$ and the pH of the blood near the normal values (Honda & Kreuzer 1966) it was decided to add a certain dose of carbon dioxide to the gas with reduced oxygen content. The aim was to see whether this CO_2 addition would change the effects of the hypoxia described above.

RESULTS OF INCREASED CARBON DIOXIDE TENSION IN AIR

The results hitherto presented have shown a variation in growth on alteration of the inspired oxygen tension. It has also been demonstrated that the decrease in growth at reduced oxygen is not due to the concomitant reduction of the carbon dioxide tension during the hypoxaemic hyperventilation. These observations on hypoxaemia with and without hypocapnia also represent observations on decreased (Chapter 4) and undecreased (Chapter 5) carbon dioxide tension. As the effects on growth were not changed by the difference in carbon dioxide tension the conclusion can be drawn that a reduction of carbon dioxide does not influence on the growth as measured here with the limitation of being guilty only in hypoxaemia. As mentioned in the introduction venous stasis has been held responsible by various authors for stimulated growth in general and this makes the study of the carbon dioxide factor interesting. Does an increased carbon dioxide tension accelerate the growth rate for instance by a vasodilation in bone? To begin with this question can be raised irrespective of the mechanism involved.

It was considered advisable to start with a fairly small dose to avoid carbon dioxide toxicity which might be present for instance as a depression on the cartilage cell metabolism. The percentages chosen were 3 per cent, 5 per cent and 7 per cent. Higher doses are not tolerated by human volunteers (Fig. 12). Much higher doses can be given to animals before death occurs but it was considered to be of little interest in this investigation to further increase the carbon dioxide tension because of the pronounced effects on the general condition of animals under such circumstances.

A Three per cent carbon dioxide in air at 1 atm abs. with growth recording periods of 24 hrs

The results are given in Table 25 with control animals in Table 26. The statistical comparison between changes in test and control showed no differences. There were no particular changes in the mean values between the seven consecutive days studied.

Figure 11

Longitudinal growth of the proximal tibial metaphysis in rabbits at exposure to a gas mixture with 10 % of oxygen and 5 % of carbon dioxide in nitrogen at normal barometric pressure. Exposure time 8 hrs during period 0. Growth recordings by oxytetracycline labelling for seven consecutive days. Mean growth changes in microns from day to day measured within the same animal. Figures made continuous by overlapping observations in period +1 and +3.

cent oxygen all in nitrogen the rectal temperature of the control animals was in mean 38.6 °C and in the test group 37.9°C. The difference was significant which means that the temperature factor had to be taken into consideration later (Chapter 7). Furthermore this hyperventilation when influencing on the temperature could be expected to influence also on the water balance of the animals. To evaluate this possibility 6 animals were exposed as above and the haematocrit and the haemoglobin values of venous blood was determined before and immediately after. The haematocrit values ranged between 33 and 44 per cent but without differences between tests and controls. The haemoglobin was between 9.6 and 13.6 g per cent also with no difference between tests and controls.

It was considered indicated also to study the possible role played by carbon dioxide alone when given in increased dose at an unreduced oxygen partial pressure.

temperatures were measured immediately at the end of the 8 hrs but no significant difference was observed in this case in contrast to the study of 10 per cent O + 5 per cent CO₂ in nitrogen. Therefore no determination was performed on haemoglobin and haematocrite values because the hyperventilation even when inducing a reduced temperature did not alter these values (Chapter 6)

DISCUSSION

The activity of investigation into the bone growth and related problems is considerable. A search of the literature through the years 1964—67 by the MEDLARS system of automatic data analysis at the Karolinska Institutet Stockholm Sweden yielded 612 references on *Bone Growth* and 377 on *Blood Flow in Bone and Extremities*. The aspect from which the author has investigated this problem concerning endochondral growth of bones seems not to be reported but it has been used in tissue cultures and in studies on wound healing fracture healing and periosteal proliferation (Chapter 1). Changes in the blood circulation arterial as well as venous is closely interrelated to changes in the tensions of the respiratory gases of the tissues besides the concomitant alteration in the transport of other components of the blood. It was decided that the growth in length of bones should be analysed at a primary change in the gaseous pressures to see whether a knowledge in this uninvestigated sector of bone physiology would shed some light on the clinical problem of leg length inequality.

A sensitive method for recording of growth in length was necessary because the exposures to the test gases had to be short if acclimatization reactions (Altland & Highman 1952) and the toxicity of oxygen (Bean 1945) were to be avoided (Chapter 2). This means that a daily recording of the growth had to be possible because the oxygen toxicity is induced within hours during pure oxygen breathing at increased barometric pressure both in rabbits and humans (Binger et al 1977, Bean 1964). The intravital oxytetracycline labelling method was well known at the institution and was the most sensitive for quantitative measurements of daily growth in length in rabbits (Hansson 1967). Therefore the choice of this method needs no further discussion.

With the aim of inducing alteration first in the oxygen tension and secondly also in the carbon dioxide tension of the blood it seemed convenient to perform this by respiratory gas changes. In this way it was possible to utilize data from

This part of the investigation had not demonstrated any effects on the longitudinal growth rates of the proximal tibial metaphysis during or after increase in the respiratory carbon dioxide concentrations to 3—7 per cent for 8 hrs. and with an observation time of 6 consecutive periods of 24 hrs., thus covering the maturing time of the epiphyseal cartilage cells in the growth plate (Messier & Leblond 1960). The partial pressure of carbon dioxide in venous blood is in man about 50 mm Hg (Patterson et al. 1955) which would correspond to about 6.5 per cent CO₂ in air at a pressure of 760 mm Hg. The use of 7 per cent here has consequently been well above the normal venous blood tension. The partial pressures used in this investigation must have been sufficiently high for the purpose of the study. A further elevation of the carbon dioxide tension up to growth depressing concentrations was beyond the scope of this study.

Figure 14

Oxygen dissociation curves of maternal and fetal bloods from rabbits near term
(After Barron D H Meschia G *Symposium on Biol* 19 93 1954)

and so on. These differences are not unknown (Dittmer & Grebe 1958) but in this investigation the absolute quantitative changes were of less importance than the principal alterations induced. For this reason it was considered to be unnecessary to make special analyses of the blood gas tensions pH and so on in the rabbits used for the study. For the ages used in this investigation it can be deduced from the curves of haemoglobin dissociation at birth and at adulthood (Fig. 14) that the actual values have been somewhere between the two curves and very near the human dissociation curve (Dittmer & Grebe 1958).

The investigation begins with testing of increased oxygen tensions (Chapter 3) with omission of the intervals earlier tried (Persson 1967). It proved to be above the limit of oxygen toxicity to use 100 per cent oxygen for 8 hrs at 2 atm abs. as judged by autopsy of the lungs of the animals. There was however

the literature of respiratory physiology and at the same time to perform the experiments without direct influences on the extremities, as for instance in perfusion techniques. This would introduce other factors influencing on growth such as trauma, immobilisation, venous stasis or denervation (Sunden 1967). It was decided as a compromise between reduction of errors of the method and avoiding of the oxygen toxicity to use 8 hrs of treatment with increased oxygen tensions. The same times were used for the whole investigation to make comparisons easier, although the toxicity factors of the different exposures were not the same. The treatment was given only once and continuously during the end of the day named period 0 (Fig. 2 and 3). This localisation was intended to prevent coverings of eventually diaphasic responses (Persson 1967).

Experimental works with growing rabbits always result in a considerable mortality during the period when they are no longer feeding from the mother. To reduce errors from this, defined conditions were set out for exclusion of aberrant animals in a way which was intended not to influence on the reliability of the results obtained (Chapter 2). By the 6 principles for exclusion the total number of animals in this investigation was reduced from 1079 to 948 which seems reasonable in rabbits of this age (Table 1). Of this material 737 rabbits were controls with notes on age, weight and longitudinal growth of the proximal tibial metaphysis all measured on the same day. With the rabbits arranged in groups of 5 days difference in age there was found to be a significant or highly significant positive correlation between the weight and the growth in length (Chapter 2). This is not in accordance with Hansson (1967) but his analysis was performed within each litter and with animals excluded below defined weight limits.

The statistical treatment of the material is described in Chapter 2. It was decided that comparisons of changes in growth should be based on changes within each animal thereby reducing the variation in the samples regarding their growth in absolute values. Only three consecutive time periods of growth were measured in each animal and to cover the total maturing time of the cartilage cells (Kember 1960, Messier & Leblond 1960) three overlapping series of animals were used in each study thereby giving a series of 7 consecutive days of growth (Fig. 2 and 3). The mean differences of growth from day to day within the same animal are illustrated in the figures. Some figures are in addition made up as vertical comparisons of the growth in absolute mean values between a test group and a control group both made up of litter mates.

Some basic principles and data from the respiratory physiology are mentioned in the end of chapter 2, concerning mostly alveolar and blood gas tensions at the partial pressures of gases used in this investigation. Many of these values are from human experiments but as the rabbit has about the same oxygen dissociation curve (Fig. 14) of haemoglobin and the same pH the same principles apply to them, although the absolute values can be a bit different because of differences in body temperature, temperature regulation, respiratory dead space

much. During period -1 the growth differs only 7 microns in mean value from period 0 it differs 22 microns and during period +1 it differs 23 microns between test and control. The same difference in absolute growth rates between test and control remains during period +1 to +3 (Tables 6 and 7) but in the last series of animals covering periods +3 to +5 there seems to be no difference in the mean values. This could be a coincidence but it implies that the stimulation had ended after about 72 hrs that is during period +3 about. This is illustrated in Fig 7. The type of calculation used for Fig 7 has not been used for the statistics because it introduces another error which was considered to be principally larger i.e. comparison of changes in growth rates which are not within the same animal. Unless the samples are very large it can not be expected that the mean growth in the control group should be the same as in the test group as measured in absolute values of growth. It is probable that the stimulation recorded in period 0 measured to about 3 per cent above the control is so near the error of the method (Hansson 1967 Persson 1967) that it was impossible to get a significant measure of the return to a normal growth rate if this return occurs over a couple of days around period +3 thus measuring only some per cent from one day to the other. It should also be noted that at the age of rabbits used there is a normal decrease in growth rates of about 1 per cent daily (Fig 15). Variations in this could influence on occasional samples.

To conclude on the analysis of increased oxygen tensions there was found to be a small stimulation of the longitudinal growth of the tibial proximal metaphysis during breathing of 100 per cent of oxygen at 1 atm abs for 8 hrs. In the series with 24 hrs as the labelling period the increase was 3 per cent. When the labelling period was 12 hrs instead the increase should have been about 6 per cent theoretically as will be explained below. It was noted to be 5 per cent (Chapter 3). This means that the actual increase in growth during the oxygen treatment in period 0 (that is 8 hrs of the 12 or 24 hrs used as the labelling interval) should have been about 7.5 to 9 per cent above the growth rate before treatment. This conclusion can be made because of the positioning of treatment in relation to the oxytetracycline injections (Fig 2-3) in such a way that period 0 ends very close to the end of the oxygen treatment. This makes the hrs before the start of treatment still included in period 0 to have a growth rate like that of the control day named period -1 as long as there is no diurnal variation (Persson 1968). It is not possible to say if the increase in growth rate mentioned was the same during all the 8 hrs of hyperoxygenation. It is of interest to compare this degree of stimulation with the values reported after peripheral nerve division (Sunden 1967) also in rabbits and with the oxytetracycline method. In comparison between the operated and the non operated side there was a difference of 23 per cent on the sixth day after the nerve section with the higher growth rate on the paralyzed side. This seems to be a greater stimulation but it should be remembered that there might have

a small but statistically insignificant increase in growth during the oxygen treatment at 2 atm abs followed by a significant decrease in growth during the 12 hrs after withdrawal of oxygen. This might be the result of the oxygen toxicity to the lungs (Smith 1899) as it was not observed when the oxygen pressure was reduced to 100 per cent at 1 atm abs. At this tension there was no mortality and no lung changes either and the increase in growth during the treatment was now statistically significant measuring 5 per cent in absolute mean value compared to the controls. The results mentioned above were achieved with growth recording periods of 12 hrs. The decrease in growth during the time period immediately after the hyperoxygenation observed at 2 atm abs was not significant after a continuous exposure for 8 hrs at 1 atm abs of pure oxygen. When the observation time was extended for 5 days after the gas exposure (Chapter 3, C) the same changes were observed with a significant increase in growth (+3 per cent compared to the control) during the period of hyperoxygenation but with no further changes with comparison between test and control for the following 5 days. This should imply that the stimulation of growth which was observed to start during the hyperoxygenation continued for the following time periods. If it had ceased suddenly there should have been a decrease in growth again with comparison between the changes in test and control from some period to the next, and this was not the case. Only during period +5 in the test group there was a significant decrease in growth but in comparison with the changes in the control group this significance was lost. There was also a significant decrease in growth during period +1 compared to period 0 but this is of the same magnitude both in test and control. The reason for this decrease in both groups might be that the animals had been taken away from their mother for the first time during the day before and also that intravenous injections had been started the day before that. Such stress factors could have some temporary influence on the growth rate. There is also another possible factor in this decrease. From the earlier investigations of hyperoxygenation at 1 and 2 atm abs but with growth recording periods of 12 hrs reported above there had been significant signs of such a decrease. When the measuring microscopy is performed as a blind test it is possible that expectancies of changes influence on the readings within the limits of error of the labelling line identification. But the blind handling in this case will affect the control and test equally, thereby eliminating some significances when the comparison is performed between the changes in test and in the control. Returning to the observations made at 1 atm abs during 100 per cent of oxygen breathing for 8 hrs and with growth recording periods of 24 hrs the question remains to be answered if the stimulation during the exposure proceeds also on the following days which is suggested by the fact that no later decrease is statistically verified. Looking at the absolute values of growth rates (Tables 6 and 7) it seems as if the increase in growth during period 0 in the test group is lost during periods +1 but in the control group the values of growth decrease

as much. During period -1 the growth differs only 7 microns in mean value, during period 0 it differs 22 microns and during period $+1$ it differs 23 microns between test and control. The same difference in absolute growth rates between test and control remains during period $+1$ to $+3$ (Tables 6 and 7) but in the last series of animals covering periods $+3$ to $+5$ there seems to be no difference in the mean values. This could be a coincidence but it implies that the stimulation had ended after about 72 hrs that is during period $+3$ about. This is illustrated in Fig 7. The type of calculation used for Fig 7 has not been used for the statistics because it introduces another error which was considered to be principally larger i.e. comparison of changes in growth rates which are not within the same animal. Unless the samples are very large it can not be expected that the mean growth in the control group should be the same as in the test group as measured in absolute values of growth. It is probable that the stimulation recorded in period 0 (measured to about 3 per cent above the control) is so near the error of the method (Hansson 1967 Persson 1967) that it was impossible to get a significant measure of the return to a normal growth rate if this return occurs over a couple of days around period $+3$ thus measuring only some per cent from one day to the other. It should also be noted that at the age of rabbits used there is a normal decrease in growth rates of about 1 per cent daily (Fig 15). Variations in this could influence on occasional samples.

To conclude on the analysis of increased oxygen tensions there was found to be a small stimulation of the longitudinal growth of the tibial proximal metaphysis during breathing of 100 per cent of oxygen at 1 atm abs for 8 hrs. In the series with 24 hrs as the labelling period the increase was 3 per cent. When the labelling period was 12 hrs instead the increase should have been about 6 per cent theoretically as will be explained below. It was noted to be 5 per cent (Chapter 3). This means that the actual increase in growth during the oxygen treatment in period 0 (that is 8 hrs of the 12 or 24 hrs used as the labelling interval) should have been about 7.5 to 9 per cent above the growth rate before treatment. This conclusion can be made because of the positioning of treatment in relation to the oxytetracycline injections (Fig 2-3) in such a way that period 0 ends very close to the end of the oxygen treatment. This makes the hrs before the start of treatment still included in period 0 to have a growth rate like that of the control day named period -1 as long as there is no diurnal variation (Persson 1968). It is not possible to say if the increase in growth rate mentioned was the same during all the 8 hrs of hyperoxygenation. It is of interest to compare this degree of stimulation with the values reported after peripheral nerve division (Sunder 1967) also in rabbits and with the oxytetracycline method. In comparison between the operated and the non operated side there was a difference of 23 per cent on the sixth day after the nerve section with the higher growth rate on the paralyzed side. This seems to be a greater stimulation but it should be remembered that there might have

been a certain retardation also on the control side, due to the catabolic phase after the operation. This factor has been shown to influence on the growth rate measured with the same technic by *Hansson* (1967). He recorded a relative stimulation of growth after medullary plugging of tibia measuring up to 10 per cent above the control side. This is more of the magnitude measured in the present study. It is not possible with the available information, to say whether the calculated growth acceleration (+7.5 to 9 per cent) observed during hyperoxygenation was near or far from the maximal growth rate of the cartilage that is if oxygen, at least for a short time, can speed up the growth rate fully, or if other factors are of greater importance in addition.

The effects on growth seen during oxygen breathing may theoretically be due to some secondary factor and not to the changes in oxygen availability itself. However breathing 100 per cent of oxygen does not seem to influence on arterial pH and pCO₂ (*Dittmer & Grebe* 1958) although smaller changes occasionally are reported. Heart rate, blood pressure and vascular resistance are also nearly unchanged (*Egger et al.* 1962). Ventilation volumes have been reported to be slightly decreased (*Hejneman* 1943) but also to be increased (*Lambertsen et al.* 1953). It has been advocated to be an accumulation of carbon dioxide in tissues during hyperbaric oxygenation, due to blocking of the haemoglobin by the oxygen (*Bean* 1945). *Lambertsen et al.* (1953) have shown that this is not the case in rabbit breathing 3.5 atmospheres of pure oxygen. This was investigated by analysis of subcutaneous carbon dioxide gas depots and there was no increase above the controls until after 4 hrs of oxygen treatment that is when the pulmonary toxicity influences on the gas exchanges. Thus there is no unequivocal support for the possibility that the growth effects of oxygen is mediated by the abovementioned factors. Changes in the respiratory oxygen tensions influence also on the blood circulation which will be discussed below in connection with decreased oxygen tensions and changes in the carbon dioxide tension which are also vasoactive.

Results of decreased oxygen tensions are given in Chapter 4. This part of the investigation comprises 461 accepted animals distributed on hypoxic conditions corresponding to air breathing at 3000, 4000, 5000 and 6000 meters altitude in a hypobaric chamber and on exposures to 12 and 10 per cent of oxygen in nitrogen at normobaric environmental pressure. The experiments showed that 3000 meters (corresponding to a pO₂ of about 108 mm Hg) did not statistically affect the growth rates of the proximal tibial metaphysis for the time of exposure used. At 4000 meters there was a highly significant decrease in growth from the day of exposure to the day after and another highly significant increase in growth from the first day after to the second day after exposure (Chapter 4 F). The arithmetic mean of the decrease was 11 per cent and of the following increase it was 5 per cent in comparison between changes in the test and in

the control group. The result at 5000 meters were about the same. At 6000 meters the effects were still more pronounced now with a highly significant decrease in growth on the day of treatment compared to the day before measuring 9 per cent in mean difference. This was followed by a further decrease of 70 per cent to the day after treatment, still highly significant. From period +1 to period +2 after treatment there was again a significant increase in growth, now measuring a little more than 4 per cent only.

These results were obtained in a hypobaric chamber. To rule out the possibility that the effects on growth were caused by other factors than the reduction in the oxygen pressure the analysis was continued by testing 12 per cent and 10 per cent of oxygen in nitrogen at a normal barometric pressure. The same tendencies were again observed with a decrease in growth from the day before to the day of treatment measuring 7 per cent at 10 per cent of oxygen. From the day of treatment to the day after there was another significant decrease of 7 per cent. In this connection it should be remembered that the relation between exposure and measuring periods was the same as in the pure oxygen studies. This means that the reduction of 7 per cent recorded during the hypoxic exposure implied that the actual reduction were three times greater that is about 21 per cent during the 8 hrs of treatment within the 24 hrs of oxygen labelling in period 0. If the same considerations are applied to the studies on simulated altitudes we can deduce that the decrease in growth during hypoxic conditions (4000—6000 meters) were between 10.5 per cent and 33 per cent. The growth rate during the day after treatment was in general a little less depressed than these figures contrary to the impression given by the illustrations (Fig 8 and 9). Returning to the study of 10 per cent of oxygen in nitrogen there was no statistical significance in the increase of growth from period +1 to +2 contrary to the altitude exposures. Looking at the absolute values however there was such an increase which was significant in the 10 per cent oxygen test group and not significant in the corresponding control group. With comparison between the two groups this significance was lost. The mean difference between periods +1 and +2 was +6 per cent which is the same magnitude as earlier observed in the hypobaric chamber. The samples used at the 10 per cent of oxygen test were however fairly small at these time periods (10 and 9 animals in test and control). It was therefore concluded on the basis of the total material that the effects on the longitudinal growth were the same whether the hypoxia was caused by means of a hypobaric chamber or by exposing the animals to a gas mixture with oxygen of the corresponding partial pressure. For the utilized time of exposure it can further be concluded that 3000 meters does not influence on growth that is a barometric pressure of about 520 mm Hg and an oxygen partial pressure of about 110 mm Hg compared to the normal pressure 159 mm Hg. At 4000 and 5000 meters there were pronounced but temporary effects on growth. At 6000 meters or a 10 per cent of oxygen (pO₂ about 75 mm Hg) the reduction was more pronounced.

been a certain retardation also on the control side, due to the catabolic phase after the operation. This factor has been shown to influence on the growth rate, measured with the same technic by *Hansson* (1967). He recorded a relative stimulation of growth after medullary plugging of tibia, measuring up to 12 per cent above the control side. This is more of the magnitude measured in the present study. It is not possible with the available information to say whether the calculated growth acceleration (+7.5 to 9 per cent) observed during hyperoxygenation was near or far from the maximal growth rate of the cartilage, that is if oxygen at least for a short time can speed up the growth rate fully, or if other factors are of greater importance in addition.

The effects on growth seen during oxygen breathing may theoretically be due to some secondary factor and not to the changes in oxygen availability itself. However, breathing 100 per cent of oxygen does not seem to influence on arterial pH and pCO_2 (*Dittmer & Grebe* 1958) although smaller changes occasionally are reported. Heart rate, blood pressure and vascular resistance are also nearly unchanged (*Egger et al* 1962). Ventilation volumes have been reported to be slightly decreased (*Hejneman* 1943) but also to be increased (*Lambertsen et al* 1953). It has been advocated to be an accumulation of carbon dioxide in tissues during hyperbaric oxygenation, due to blocking of the haemoglobin by the oxygen (*Bean* 1945). *Lambertsen et al* (1953) have shown that this is not the case in rabbit breathing 3.5 atmospheres of pure oxygen. This was investigated by analysis of subcutaneous carbon dioxide gas deposits and there was no increase above the controls until after 4 hrs of oxygen treatment, that is when the pulmonary toxicity influences on the gas exchanges. Thus there is no unequivocal support for the possibility that the growth effects of oxygen is mediated by the abovementioned factors. Changes in the respiratory oxygen tensions influence also on the blood circulation which will be discussed below in connection with decreased oxygen tensions and changes in the carbon dioxide tension, which are also vasoactive.

Results of decreased oxygen tensions are given in Chapter 4. This part of the investigation comprises 461 accepted animals distributed on hypoxic conditions corresponding to air breathing at 3000, 4000, 5000 and 6000 meters altitude in a hypobaric chamber and on exposures to 12 and 10 per cent of oxygen in nitrogen at normobaric environmental pressure. The experiments showed that 3000 meters (corresponding to a pO_2 of about 108 mm Hg) did not statistically affect the growth rates of the proximal tibial metaphysis for the time of exposure used. At 4000 meters there was a highly significant decrease in growth from the day of exposure to the day after and another highly significant increase in growth from the first day after to the second day after exposure (Chapter 4 F). The arithmetic mean of the decrease was 11 per cent and of the following increase it was 5 per cent in comparison between changes in the test and in

at a given oxygen tension *Lennox and Gibbs* (1932) have determined the the oxygen and carbon dioxide contents of arterial and venous femoral blood in humans inhaling various mixtures containing these gases and nitrogen. At an oxygen concentration of 6—12 per cent in nitrogen the arterial oxygen content decreased from 17.5 to 16.5 vol per cent and the venous oxygen content from 13.5 to 12.3 vol per cent. At the same time the arterial carbon dioxide content decreased from 51.4 to 49.5 vol per cent and the venous carbon dioxide content changed from 54.1 to 54.3 vol per cent as a mean of 4 test subjects. When 4—6 per cent of carbon dioxide was added to the same oxygen concentration the arterial oxygen content decreased from 18.8 to 16.5 vol per cent the venous oxygen content from 15.6 to 13.3 vol per cent and the carbon dioxide content increased in arterial blood from 47.7 to 49.1 vol per cent and in venous blood from 50.2 to 51.0 vol per cent. The changes recorded means changes from normal air breathing to the test gas specified after 10—15 min. The referred values imply that the addition of carbon dioxide was enough to counteract the reduction in carbon dioxide tension caused by hypoxic hyperventilation at an oxygen concentration of 8—12 per cent in nitrogen. About the same inspiratory gas concentrations were used in the present investigation. It also means that the addition of carbon dioxide did not reduce the magnitude of decrease in the arterial oxygen content during 8—12 per cent of oxygen breathing. This could have been suspected for the reason that the added carbon dioxide further increases the hyperventilation caused by the hypoxia. On the other hand it could also have been expected to be a reduced oxygen content in the blood after the addition of carbon dioxide due to the increased acidity and the resulting 'Bohr effect' on the haemoglobin dissociation curve which gives a reduction in the oxygen binding capacity at increased carbon dioxide tensions (*Steen* 1968). The reported oxygen contents above (*Lennox & Gibbs* 1932) showed this tendency. It is possible that these two counteracting effects (hyperventilation and Bohr effect) of the added carbon dioxide explain why no difference was demonstrated in the growth rate studies. Effects on the blood flow could also be expected from the added carbon dioxide (see later).

For a further understanding of the possible effects caused by carbon dioxide on growth it was studied during normoxic conditions also. Addition of carbon dioxide to air could influence on growth rate by influence on the oxygen tensions due to hyperventilatory increase of the alveolar ventilation or to Bohr-effects on the haemoglobin dissociation curve as discussed above for the hypoxaemia experiments. It could also influence on the bone blood flow (see later). Growth recordings were made at 3, 5 and 7 per cent of carbon dioxide in air at 1 atm. for 8 hrs. No significant effects on the growth rates were observed (Chapter 6). Observations were made for five days after the end of the exposures. An increased growth could have been expected by the fact that the hyper-

ced but now not fully reversible. This is in accordance with Campbell's find. (1935), that rabbits were able to acclimatize to 12 per cent but not to 10 per cent of oxygen at which they did not keep their normal weight. If the 15th degrees of hypoxia are transformed to alveolar oxygen partial pressure (La 1961) and from that to haemoglobin oxygen saturation (Roughton 1965) it is found that there was no influence on the growth rate at an arterial haemoglobin oxygen saturation above 90 per cent and that the changes were evident but lasted only for 24 hrs after exposure, if the haemoglobin oxygen saturation was somewhere between 70 and 90 per cent. If the oxygen saturation was reduced to about 65 per cent the mean growth rates did not fully return to the normal levels for the observation time used that is up to 5 days after the hypoxia.

Reduced oxygen tension induces a hyperventilation which in turn lowers the carbon dioxide tension (Chapter 2). On the other hand pure oxygen breathing could have a slight tendency to increase the tissue carbon dioxide content by reducing the ventilation and by blocking parts of the carbon dioxide transport (Bean 1945). For these two reasons it seemed necessary to study effects from alteration in the carbon dioxide tensions also. Actually the study reported above on decrease in oxygen represents a study on decrease in carbon dioxide as well. Taking the 10 per cent oxygen in nitrogen for example, this represents a condition with the alveolar pO_2 lowered from about 100 to about 34 mm Hg and at the same time a lowering of the alveolar pCO_2 from 40 to about 30 mm Hg in humans (Luft 1961). By adding 5 per cent carbon dioxide to the 10 per cent of oxygen in nitrogen it was considered possible to counteract the out washing of the carbon dioxide during the hyperventilation. In this way it should be possible to compare the effects on growth from low oxygen + low carbon dioxide with a condition of low oxygen alone.

In Chapter 5 results are presented from testing of ten per cent of oxygen in combination with five per cent of carbon dioxide in nitrogen. A comparison of the changes in growth from day to day between test and control showed that there was a decrease in growth between the day before and the day of exposure measuring 4 per cent in mean a further decrease of 8 per cent during the 24 hrs after exposure (+1) and finally an increase during the next day (+2) measuring 8 per cent. All these differences between the test group and the control group were highly significant. This means that the effects on growth in length of the metaphysis were about the same in the hypoxic experiments whether the carbon dioxide tension was allowed to be reduced by the hyperventilation or not. This in turn means that the change in growth was induced by the changes in oxygen tension.

At this point it is of interest to discuss the differences between hypocapnic and normocapnic hypoxia which differ with regard to the haemoglobin dissociation curves leading to differences in the amount of oxygen available

at a given oxygen tension *Lennox and Gibbs* (1932) have determined the oxygen and carbon dioxide contents of arterial and venous femoral blood in humans inhaling various mixtures containing these gases and nitrogen. At an oxygen concentration of 6–12 per cent in nitrogen the arterial oxygen content decreased from 17.5 to 16.5 vol per cent and the venous oxygen content from 13.5 to 12.3 vol per cent. At the same time the arterial carbon dioxide content decreased from 51.4 to 49.5 vol per cent and the venous carbon dioxide content changed from 54.1 to 54.3 vol per cent as a mean of 4 test subjects. When 4–6 per cent of carbon dioxide was added to the same oxygen concentration the arterial oxygen content decreased from 18.8 to 16.5 vol per cent, the venous oxygen content from 15.6 to 13.3 vol per cent and the carbon dioxide content increased in arterial blood from 47.7 to 49.1 vol per cent and in venous blood from 50.2 to 51.0 vol per cent. The changes recorded means changes from normal air breathing to the test gas specified after 10–15 min. The referred values imply that the addition of carbon dioxide was enough to counteract the reduction in carbon dioxide tension caused by hypoxic hyperventilation at an oxygen concentration of 8–12 per cent in nitrogen. About the same inspiratory gas concentrations were used in the present investigation. It also means that the addition of carbon dioxide did not reduce the magnitude of decrease in the arterial oxygen content during 8–12 per cent of oxygen breathing. This could have been suspected for the reason that the added carbon dioxide further increases the hyperventilation caused by the hypoxia. On the other hand it could also have been expected to be a reduced oxygen content in the blood after the addition of carbon dioxide due to the increased acidity and the resulting 'Bohr effect' on the haemoglobin dissociation curve which gives a reduction in the oxygen binding capacity at increased carbon dioxide tensions (*Steen* 1968). The reported oxygen contents above (*Lennox & Gibbs* 1932) showed this tendency. It is possible that these two counteracting effects (hyperventilation and Bohr effect) of the added carbon dioxide explain why no difference was demonstrated in the growth rate studies. Effects on the blood flow could also be expected from the added carbon dioxide (*see later*).

For a further understanding of the possible effects caused by carbon dioxide on growth it was studied during normoxic conditions also. Addition of carbon dioxide to air could influence on growth rate by influence on the oxygen tensions due to hyperventilatory increase of the alveolar ventilation or to Bohr effects on the haemoglobin dissociation curve as discussed above for the hypoxaemia experiments. It could also influence on the bone blood flow (*see later*). Growth recordings were made at 3, 5 and 7 per cent of carbon dioxide in air at 1 atm. abs. for 8 hrs. No significant effects on the growth rates were observed (Chapter 6). Observations were made for five days after the end of the exposures. An increased growth could have been expected by the fact that the hyper

ced but now not fully reversible. This is in accordance with Campbell's findings (1935), that rabbits were able to acclimatize to 12 per cent but not to 10 per cent of oxygen at which they did not keep their normal weight. If the tested degrees of hypoxia are transformed to alveolar oxygen partial pressure (Luft 1961) and from that to haemoglobin oxygen saturation (Roughton 1965) it is found that there was no influence on the growth rate at an arterial haemoglobin oxygen saturation above 90 per cent and that the changes were evident but lasting only for 24 hrs after exposure if the haemoglobin oxygen saturation was somewhere between 70 and 90 per cent. If the oxygen saturation was reduced to about 65 per cent the mean growth rates did not fully return to the normal levels for the observation time used, that is up to 5 days after the hypoxia.

Reduced oxygen tension induces a hyperventilation, which in turn lowers the carbon dioxide tension (Chapter 2). On the other hand pure oxygen breathing could have a slight tendency to increase the tissue carbon dioxide content by reducing the ventilation and by blocking parts of the carbon dioxide transport (Bean 1945). For these two reasons it seemed necessary to study effects from alteration in the carbon dioxide tensions also. Actually the study reported above on decrease in oxygen represents a study on decrease in carbon dioxide as well. Taking the 10 per cent oxygen in nitrogen for example, this represents a condition with the alveolar pO_2 lowered from about 100 to about 34 mm Hg, and at the same time a lowering of the alveolar pCO_2 from 40 to about 30 mm Hg in humans (Luft 1961). By adding 5 per cent carbon dioxide to the 10 per cent of oxygen in nitrogen it was considered possible to counteract the out washing of the carbon dioxide during the hyperventilation. In this way it should be possible to compare the effects on growth from low oxygen + low carbon dioxide with a condition of low oxygen alone.

In Chapter 5 results are presented from testing of ten per cent of oxygen in combination with five per cent of carbon dioxide in nitrogen. A comparison of the changes in growth from day to day between test and control showed that there was a decrease in growth between the day before and the day of exposure, measuring 4 per cent in mean, a further decrease of 8 per cent during the 24 hrs after exposure (+1) and finally an increase during the next day (+2) measuring 8 per cent. All these differences between the test group and the control group were highly significant. This means that the effects on growth in length of the metaphysis were about the same in the hypoxic experiments whether the carbon dioxide tension was allowed to be reduced by the hyperventilation or not. This in turn means that the change in growth was induced by the changes in oxygen tension.

At this point it is of interest to discuss the differences between hypocapnic and normocapnic hypoxia which differ with regard to the haemoglobin dissociation curves leading to differences in the amount of oxygen available

at a given oxygen tension *Lennox and Gibbs (1932)* have determined the the oxygen and carbon dioxide contents of arterial and venous femoral blood in humans inhaling various mixtures containing these gases and nitrogen. At an oxygen concentration of 6—12 per cent in nitrogen the arterial oxygen content decreased from 17.5 to 16.5 vol per cent and the venous oxygen content from 13.5 to 12.3 vol per cent. At the same time the arterial carbon dioxide content decreased from 51.4 to 49.5 vol per cent and the venous carbon dioxide content changed from 54.1 to 54.3 vol per cent as a mean of 4 test subjects. When 4—6 per cent of carbon dioxide was added to the same oxygen concentration the arterial oxygen content decreased from 18.8 to 16.5 vol per cent the venous oxygen content from 15.6 to 13.3 vol per cent and the carbon dioxide content increased in arterial blood from 47.7 to 49.1 vol per cent and in venous blood from 50.2 to 51.0 vol per cent. The changes recorded means changes from normal air breathing to the test gas specified after 10—15 min. The referred values imply that the addition of carbon dioxide was enough to counteract the reduction in carbon dioxide tension caused by hypoxic hyperventilation at an oxygen concentration of 8—12 per cent in nitrogen. About the same inspiratory gas concentrations were used in the present investigation. It also means that the addition of carbon dioxide did not reduce the magnitude of decrease in the arterial oxygen content during 8—12 per cent of oxygen breathing. This could have been suspected for the reason that the added carbon dioxide further increases the hyperventilation caused by the hypoxia. On the other hand it could also have been expected to be a reduced oxygen content in the blood after the addition of carbon dioxide due to the increased activity and the resulting Bohr effect on the haemoglobin dissociation curve which gives a reduction in the oxygen binding capacity at increased carbon dioxide tensions (*Steen 1968*). The reported oxygen contents above (*Lennox & Gibbs 1932*) showed this tendency. It is possible that these two counteracting effects (hyperventilation and Bohr effect) of the added carbon dioxide explain why no difference was demonstrated in the growth rate studies. Effects on the blood flow could also be expected from the added carbon dioxide (see later).

For a further understanding of the possible effects caused by carbon dioxide on growth it was studied during normoxic conditions also. Addition of carbon dioxide to air could influence on growth rate by influence on the oxygen tensions due to hyperventilatory increase of the alveolar ventilation or to Bohr effects on the haemoglobin dissociation curve as discussed above for the hypoxaemia experiments. It could also influence on the bone blood flow (see later). Growth recordings were made at 3, 5 and 7 per cent of carbon dioxide in air at 1 atm. abs for 8 hrs. No significant effects on the growth rates were observed (Chapter 6). Observations were made for five days after the end of the exposures. An increased growth could have been expected by the fact that the hyper-

ventilation that is induced increases the alveolar oxygen tension. Furthermore an increased oxygen availability in the bone could have been caused by the Bohr effect. In contrast to its consequences during hypoxic conditions, it has theoretically a promoting effect on the oxygen transport during normoxia. This is due to the fact that the dissociation curves at normocapnia and at hypercapnia coincide at a normal arterial oxygen tension but divide at a reduced oxygen tension liberating more oxygen in the capillary system. The gain in oxygen availability caused by this mechanism is probably too small to give measurable effects on growth, and the same is probably the case with the gain due to hyperventilation. The moderate increase in growth caused by a five-fold oxygen tension (Chapter 3) makes this conclusion reasonable. On the other hand it could have been a slight depressing effect on the cell metabolism from the increased carbon dioxide tension counteracting the increased oxygen availability. Finally, it is also possible that carbon dioxide influences on the bone blood flow (see later).

In addition to the discussion of the separate results above, some common factors will be considered below, that is the possible effects caused by changes in temperature and in the bone blood flow.

As mentioned temperature has been considered to be a possible regulant of growth rate in bones although no unequivocal results have been presented as to the possibilities of using it as a stimulant of growth (Chapter 1). Rabbits are known to regulate temperature by breathing and this fact introduces the possibility that effects on growth at changes in the gaseous environment are concomitant with alterations in the body temperature. To evaluate this possibility rectal temperatures were recorded in some of the series. Exposure to 100 per cent of oxygen at 1 atm abs did not influence on the temperatures (Chapter 3). In this case the conclusion is that the increase in growth simultaneously recorded was not due to change in temperature. It was expected to be a maximal hyperventilation at exposure to a combination of decreased oxygen and increased carbon dioxide tensions. This test was therefore chosen for the next determination of temperatures that is the exposure to 10 per cent of oxygen and 5 per cent of carbon dioxide in nitrogen (Chapter 5). There was found to be a significant decrease in body temperature at the end of the exposure measuring in mean 0.7°C . In this case there were concomitant decreases in temperature and in growth. To see whether this decrease was due to the hypoxia or to the increased carbon dioxide tension in the inspired gas temperature recordings were also performed at the same oxygen tension but without addition of carbon dioxide. It was performed on 7 animals after 8 hrs at 5900 meters corresponding to an oxygen concentration of 10 per cent at 1 atm abs. No changes were observed compared to the temperatures before exposure and to 5 control animals. Addition of 7 per cent carbon dioxide to

air for 8 hrs did not change the temperature either (Chapter 6) The conclusion is that the changes in growth were not concomitant with changes in the rectal temperature except in one experiment which does not warrant any conclusion as to the possibility that the growth can be altered by local change in temperature Determination of haemoglobin content and haematocrit value (Chapter 5) did not show any change during the exposure indicating that the decrease in temperature was coincident with any significant loss of fluid

The next special factor is the influences on the blood flow from the alteration in gas tensions studied It is well documented that both oxygen and carbon dioxide may be vasoactive altering the blood flow with changes in tension This has been studied regarding the femoral blood flow (Lennox & Gibbs 1932) Increased oxygen tensions gave slightly reduced flow rates (Bird & Telfer 1966) decreased oxygen tensions gave considerable increases (Boon & Marotta 1964) and finally increased carbon dioxide tensions gave slight increases in sympathetomized limbs but slight decreases in normal limbs (Steck & Gellhorn 1939) There are however no reports on the changes in the intraosseous blood flow under the circumstances mentioned Therefore this was specially studied using the heat clearance method described by Sunden (1967) and the gas tensions used in the present investigation There turned out to be no consistent effects measurable on the blood flow in the epiphysis These experiments will be separately published (Persson & Sunden 1968) The indication at present is that the effects on growth described in this investigation were achieved without measurable changes in the bone blood flow

The next part of the discussion will be devoted to the time lags between the exposures and the recorded effects on growth with the intention of evaluating which cells of the cartilage plate that have highest sensitivity to the treatments This problem is presented in Chapter 4 where determinations of the height of the cartilage plate are reported For the following discussion a summarizing figure (Fig 16) is given concerning some principal growth effects obtained with increased and decreased oxygen tensions and increased carbon dioxide tensions The figure depicts the growth ratios between test and control for each day with litter mates in both groups It is made up from the absolute values of growth in microns The overlapping samples in the time periods +1 and +3 have been summarized From this figure (Fig 16) it is clear that the effects on growth were recorded already during the exposure to the artificial gas mixtures rich or poor in oxygen This means that the effect was elicited in the zone of degenerating cells where the tetracycline was built in labelling the growth process The curves give the impression that the hypoxic depression

ventilation that is induced increases the alveolar oxygen tension. Furthermore an increased oxygen availability in the bone could have been caused by the Bohr effect. In contrast to its consequences during hypoxic conditions it has theoretically a promoting effect on the oxygen transport during normoxia. This is due to the fact that the dissociation curves at normocapnia and at hypercapnia coincide at a normal arterial oxygen tension but divide at a reduced oxygen tension liberating more oxygen in the capillary system. The gain in oxygen availability caused by this mechanism is probably too small to give measurable effects on growth, and the same is probably the case with the gain due to hyperventilation. The moderate increase in growth caused by a fivefold oxygen tension (Chapter 3) makes this conclusion reasonable. On the other hand it could have been a slight depressing effect on the cell metabolism from the increased carbon dioxide tension, counteracting the increased oxygen availability. Finally, it is also possible that carbon dioxide influences on the bone blood flow (see later).

In addition to the discussion of the separate results above some common factors will be considered below, that is the possible effects caused by changes in temperature and in the bone blood flow.

As mentioned temperature has been considered to be a possible regulator of growth rate in bones although no unequivocal results have been presented as to the possibilities of using it as a stimulant of growth (Chapter 1). Rabbits are known to regulate temperature by breathing and this fact introduces the possibility that effects on growth at changes in the gaseous environment are concomitant with alterations in the body temperature. To evaluate this possibility rectal temperatures were recorded in some of the series. Exposure to 100 per cent of oxygen at 1 atm abs. did not influence on the temperatures (Chapter 3). In this case the conclusion is that the increase in growth simultaneously recorded was not due to change in temperature. It was expected to be a maximal hyperventilation at exposure to a combination of decreased oxygen and increased carbon dioxide tensions. This test was therefore chosen for the next determination of temperatures that is the exposure to 10 per cent of oxygen and 5 per cent of carbon dioxide in nitrogen (Chapter 5). There was found to be a significant decrease in body temperature at the end of the exposure measuring in mean 0.7°C. In this case there were concomitant decreases in temperature and in growth. To see whether this decrease was due to the hypoxia or to the increased carbon dioxide tension in the inspired gas temperature recordings were also performed at the same oxygen tension but without addition of carbon dioxide. It was performed on 7 animals after 8 hrs at 5900 meters corresponding to an oxygen concentration of 10 per cent at 1 atm abs. No changes were observed compared to the temperatures before exposure and to 5 control animals. Addition of 7 per cent carbon dioxide to

Figure 15

Growth rate from the proximal growth plate of the tibia of rabbits according to Hansson (1967)

bility due to circulatory disturbances (Ackerman & Brunkley 1966) as for instance in pathological fracture healing (Coulson et al 1966 Goulon et al 1968). Regarding the introductory question of venous stasis or arterial hyperaemia as the possible mechanism behind unilateral stimulation of bone growth this investigation does not positively support the assumption that venous stasis should stimulate the growth. Arterial hyperaemia seems more in line with the

(10 per cent O + N) is greater during the day after exposure than during the exposure. This is due to the fact earlier mentioned that the day of exposure includes about 16 hrs of normal growth before the 8 hrs of treatment and decrease in growth. This means that the actual growth rate under the hypoxic condition was somewhat three times greater than recorded in the figure. In other words the decrease in growth rate is about the same during the hypoxic exposure as during the following 24 hrs (period +1). If the same reasoning is applied to the pure oxygen breathing it would imply that the growth in period 0, recorded in Fig. 16 as a stimulation of 4 per cent in reality comprised 16 hrs of normal growth rate and 8 hrs of about 12 per cent increase in growth. This means that the stimulation is greater during the oxygen exposure than during the following days. The conclusion must be that the hyperoxygenation accelerated the growth during the treatment and that this acceleration slowly subsided during 1-4 days after. In conclusion it may be suggested that *degeneration and calcification of the cartilage cells is an oxygen depending process* easily disturbed by changes in the oxygen tension of blood. This could also be expected by the fact that this is the zone where the cartilage cells meet the blood vessels of the metaphysis (Trueta & Amato 1960).

The question can now be raised whether the changes in metaphyseal growth rate represent only alterations in the position of the calcifying frontier of a temporary duration or if they represent true changes in the growth in length of the bone. In other words are the effects limited to the degenerating zone or are they affecting a more extended series of cells in different stages of maturation? This problem was studied by determinations of the height of the cartilage plate in combination with the growth recordings (Chapter 4). After exposure to decreased oxygen partial pressure there was an almost significant decrease in the height of the plate indicating effects also on cartilage cells at other maturing stages than those undergoing degeneration. Measurement of the cartilage plate has not yet been made at increased oxygen tensions although it seems interesting to know, whether the recorded growth acceleration represents a temporary advancement of the calcifying frontier with a decrease in the height of the plate or if it is combined with an unchanged or increased height of the cartilage plate signifying that the stimulation also affected the younger cells of the cartilage.

The demonstrated sensitivity to changes in the oxygen tension and the lack of sensitivity to changes in the carbon dioxide tension does not mean that it should be possible to increase the height of a person by increasing the environmental oxygen tension. The oxygen toxicity especially to the lungs would very soon eliminate the stimulation, and might even result in a total decrease in growth. On the other hand the demonstrated importance of the oxygen tension might have some application in conditions of decreased oxygen availa-

SUMMARY

Leg length inequality in children is sometimes caused by one sided growth stimulation after fractures osteomyelites or arterio-venous fistulae. This knowledge has resulted in experimental and clinical attempts to induce such a stimulation in a short leg. This literature is shortly reviewed with special reference to the suggested causative factors particularly arterial hyperaemia venous stasis local temperature and the local oxygenation.

For studying the oxygen factor in this respect and secondly also the carbon dioxide factor young rabbits were exposed to changes in the partial pressures of the respiratory gases utilizing pressure chambers and artificial gas mixtures. The exposures were for 8 hrs and given only once. Defined principles were set up for exclusion of abnormal animals. The longitudinal growth of the proximal tibial metaphysis was recorded by intravital oxytetracycline labelling and ultra violet microscopy performed as a blind test.

It was found that oxygen tensions above 100 per cent at 2 atm abs was above the tolerance due to the pulmonary oxygen toxicity. At 100 per cent of oxygen at 1 atm abs there was a stimulation of growth during the exposure subsiding for about 1—4 days. When the oxygen tension was reduced below normal there was a decrease in growth during the exposure and during the following 24 hrs of about the same magnitude but thereafter the growth approached the normal. The oxygen tension limits of these effects were determined. The height of the cartilage plate seemed to be reduced one day after the hypoxia implying effects on an extended series of maturing stages of the cartilage cells. For elimination of the hyperventilatory hypocapnia under the hypoxic condition carbon dioxide was added to the low oxygen mixture without changing the growth effects. Addition of carbon dioxide to air did not influence on the growth within the doses tested. Rectal temperatures were checked without showing co-variation in more than one case.

Figure 16

Daily growth in length of the proximal tibial metaphysis in rabbits measured by oxytetracycline labelling given as growth rates of tests in per cent of growth in control groups. Respiratory gas altered for 8 hrs during period 0. Gas compositions given in figure. Ambient pressure 1 atm abs.

findings but on the other hand it can not be assumed that venous stasis is always concomitant with a decrease in the local blood flow. It is theoretically possible that a venous stasis with an increased venous pressure can be compensated by a local arteriolar dilatation keeping the pressure difference and the blood flow on a normal level. Attempts to measure the bone flow during venous stasis are so diverging in the results that this might be the case (Herzig & Root 1959, McPherson et al 1961, Valderrama & Trueta 1965, White & Stein 1965). If venous stasis stimulates growth it must not anyhow be combined with any significant reduction of the local oxygen tension unless it comprises other factors compensating for the hypoxic growth retardation.

ACKNOWLEDGEMENTS

This investigation has been carried out at the Department of Orthopedic Surgery in Lund in the new block for experimental medicine at the University Hospital and at the Laboratory of Aviation and Naval Medicine Institute of Physiology University of Lund Sweden

For encouraging interest and advice for scientific and economical leadership of the growth studying group my sincere thanks to my chief and teacher Professor Gunnar Wiberg I also owe a debt of gratitude to the late Laborator Gunnar Lundin at the Laboratory of Aviation and Naval Medicine for his skilled advice in physiological problems and for placing technical resources at my disposal For this I also give my acknowledgement to Docent Claes Lundgren

For generous help in methodological questions to Docent Lars Ingvar Hansson.

For co-operation and constructive criticism to Docent Goran Sundén and Docent Bo Siesjö

For valuable help with the statistics to Leif Pedersen B A

For secretarial and laboratory assistance especially to Laboratris Marianne Rabenius and also to Vaktmastare Arnold Herm and Instrumentmakare Leif Nilsson

For correction of the use of the English language to Dr David Haffajee

The work was supported by grants from the Medical Faculty in Lund the Alfred Osterlund's Foundation the AB Erix Foundation the Royal Physiographic Society in Lund and from the Swedish Medical Research Council (proj no B 67—17 X—2031—01 and B 68—17 X—2031—02)

Lund June 1968

Bjorn Mauritz Persson

It was concluded from the immediate effects on growth at changes in the oxygen tension, that the cartilage cells in the zone of degeneration and calcification were very sensitive implying an oxygen depending nature of this process. The lack of sensitivity to changes in the carbon dioxide tension was discussed with reference to venous stasis and arterial hyperaemia as mechanisms behind over-growth of a long bone.

EXPLANATIONS

Throughout the investigation apposition of dentine is measured in arbitrary units — measuring units (1 unit = 10 μ m)

The various technical terms used such as section interval point etc are explained on pages 35—36 and 52. The abbreviations used in Tables in the Appendix are explained on pages 46—47.

Tables with Roman numbers are collected in the Appendix.

INTRODUCTION AND PURPOSE OF THE INVESTIGATION

In the course of personal preliminary experimental investigations on the effect of the growth hormone on the rate of bone repair and lamellar bone formation it was realized that accurate quantitative determinations would offer considerable technical difficulties. Because of the constant remodelling of bone tissue the interpretation of the results could be difficult.

Bone repair has been studied by manual testing of the stability of the fractured bone (Koskinen 1959, 1965) by roentgenography with or without planimetric measurement of the callus as seen in the roentgenogram (Koskinen 1959, 1963, 1965) by examination of histologic sections (Koskinen 1959, 1965; Hulth & Olerud 1964; Pritchard 1964) by autoradiography (Koskinen 1959, 1965) by measurement of the mechanical strength of the fractured bone during healing (Lindsay & Howes 1931; McKeown, Lindsay, Harvey & Howes 1932; Falkenberg 1961; Wray & Goldstein 1966) by studying the uptake and disappearance of radioactive isotopes (Mitschak & Byron Jr 1945; Bauer 1954; Bohr 1955; Wendeberg 1961) by angiography (Goldman 1961; Hulth & Olerud 1964) by tetracycline labelling (Hulth & Olerud 1964) and by microradiography (Nilsson 1959; Hulth & Olerud 1964).

Like cancellous bone has been widely studied also with the aid of radioactive isotopes (Bauer, Carlsson & Lindquist 1961; Dainton 1964; Nordin, Smith & Glass 1964; Bauer 1966) microradiography (Howes 1966) and vital dyes such as alizarine (Harris 1960) and the tetracyclines (Harris 1960; Lee 1963, 1964; Frost, Villanueva & Roth 1960; Tapp 1966).

Among the above mentioned personal investigations interest was focused on dentine. This tissue is similar to bone but its physiology is

INTRODUCTION AND PURPOSE OF THE INVESTIGATION

In the course of personal preliminary experimental investigations on the effect of the growth hormone on the rate of bone repair and lamellar bone formation it was realised that accurate quantitative determination would offer considerable technical difficulties. Because of the constant remodelling of bone tissue the interpretation of the results could be difficult.

Bone repair has been studied by manual testing of the stability of the fractured bone (Koskinen 1959 1965) by roentgenography with or without planimetric measurement of the callus as seen in the roentgenogram (Koskinen 1959 1963 1965) by examination of histologic sections (Koskinen 1959 1965 Hultth & Olerud 1964 Pritchard 1964) by autoradiography (Koskinen 1959 1965) by measurement of the mechanical strength of the fractured bone during healing (Lindsay & Hawes 1931 McKeown Lindsay Harvey & Hawes 1932 Falkenberg 1961 Wray & Goldstein 1966) by studying the uptake and disappearance of radioactive isotopes (Marshall & Byron Jr 1945 Bauer 1954 Rohr 1955 Wendeborn 1961) by angiography (Guthman 1961 Hultth & Olerud 1964) by tetracycline labelling (Hultth & Olerud 1964) and by microradiography (Nilsson 1959 Hultth & Olerud 1964).

Immature as well as cancellous bone has been widely studied also with the aid of radioactive isotopes (Bauer Carlsson & Lindquist 1961 Dymally 1964 Nordin Smith & Glass 1964 Bauer 1966) microradiography (Jowsey 1966) and vital dyes such as alizarine (Harris 1960) and the tetracyclines (Harris 1960 Lee 1963 1964 Frost Villanueva & Roth 1960 Tapp 1966).

During the above mentioned personal investigations interest was focused on dentine. This tissue is similar to bone but its physiology is

ceeding to the investigation of dentine is a test tissue for hormonal influence it was considered necessary to re-investigate the normal rate of apposition of incisor dentine in the rat. Several experimental investigations of the action of the growth hormone have been performed on female rats. It was therefore primarily decided to confine the investigation to rats of this sex. The study was limited to the upper incisors for two reasons. First, owing to their shape, it is easier to obtain acceptable histologic sections from these teeth than from the lower incisors, and second, to keep the number of histologic sections and measurements within reasonable limits.

Since it was desired to compare dentine and bone formation, it was decided to study endosteal and periosteal bone formation, because bones in the rat have no Haversian systems (Enlow & Brown 1958).

The purposes of the present investigation were

to chart the normal pattern of apposition of dentine of the upper incisors in the female white rat

to find out whether the rate of apposition of dentine could be influenced by the administration of a hormone, and

to compare the rate of apposition of dentine and of lamellar bone

less complicated because no resorption occurs in normal dentine. It was thought that its rate of formation could be studied with comparatively simple laboratory methods. It had been realised by the Swedish anatomist Retzius as early as 1838 that "similarity between dentine and bone is closer than that suggested by the first microscopic examinations. Also other investigators have recognised such similarities (Weidenreich 1920, Orban 1957, Ørstavik 1958, 1967, Bernick & Ershoff 1964, Zussman & Itochin 1964).

According to Sognnaes (1955) the microstructural organisation of bone, enamel, dentine and cementum is comparable insofar as they all contain (a) a fibrous framework, (b) an amorphous ground substance and (c) inorganic crystals deposited in that order, whereas the vascular and cellular elements of bone, cementum, dentine and enamel decrease in significance in that sequence.

Bone and dentine resemble one another also in chemical composition and ultrastructure. In both tissues the bulk of the organic matrix consists of collagen, and the collagen in dentine is very similar to that in bone (Piez & Likins 1960, Eastoe 1964, 1967). The mineral phase in both tissues is in apatite (De Jong 1926, Gross 1926, Hodge 1930, Carlstrom & Engstrom 1956, Posner 1960).

Bone and dentine differ from one another in one essential respect: in bone, formation and resorption occur simultaneously; in normal dentine, only formation (Schour 1938, Schour & Massler 1943b, Sognnaes 1955) but, as in bone, exchange of ions takes place (Armstrong 1955, Sognnaes 1955).

In the incisors of rodents, dentine continues to form throughout the animal's life. In his studies on the parathyroid glands and calcium metabolism, Lrdheim (1911) considered the incisors of the rat to be an extremely sensitive indicator. He also stressed what may be called their kymographic properties: what was registered remained until the incisor was worn away. He compared the incisor with bone, where the continuous formation and resorption make the interpretation of a microscopic section very difficult, and recommended the use of the incisor in investigations of calcium metabolism. Also in fairly recent literature, incisor dentine formation in the rat has been described as continuous, very regular and very sensitive to experimental interference (Schour & Massler 1962).

Preliminary personal investigations showed that the rate of apposition of dentine in the upper incisors of the white rat varied in a more complicated way than previously supposed. Therefore, before pro-

EARLIER INVESTIGATIONS

MORPHOLOGY OF THE UPPER INCISORS, PARTICULARLY OF THE DENTINE AND A SHORT NOTE ON BONE FORMATION

INCISOR

(ross morphology)

According to Mummery (1924) "the distinguishing features of the rodent dentition are the presence in each jaw of a pair of long curved incisors with chisel shaped edges and growing from persistent pulps" (Figs 1—2)

Eruption of the incisors and formation of dentine occur simultaneously and continuously throughout the animal's life. This growth is normally counterbalanced by mechanical attrition at the incisal edges (Weinreb, Assif & Michaeli 1967).

The upper incisor has been described as a 210° segment of a logarithmic spiral with a lateral shear (Schour & Massler 1962) but also as a segment of a circle about 210° at 5 months of age (Addison & Appleton 1915). The length of the upper incisor along the outer convex side at 5 months of age (Addison & Appleton 1915) is 23.3 mm, the extra alveolar length 8.7 mm.

The main part of the rat incisor consists of dentine. The labial aspect and part of the lateral and medial aspects are covered with a layer of enamel, the rest with a thin layer of cement (Figs 2—3).

The longitudinal or "extrusive" growth of the incisor can be measured either as eruption rate or as attrition rate (Sessle 1966; Weinreb et al. 1967). Sessle found these values to be close to each other in the lower incisors. In the upper incisors the situation is similar. Thus according to Addison & Appleton (1915) the rate of attrition is 2.2 mm/week. Similar figures have been given by Schour & Massler (1962) and Stuben & Knuthe (1963) for the rate of eruption.

MORPHOLOGY OF THE UPPER INCISORS, PARTICULARLY OF THE DENTINE AND A SHORT NOTE ON BONE FORMATION

INCISOR

Cross morphology

According to Mummery (1924) "the distinguishing features of the rodent dentition are the presence in each jaw of a pair of long curved incisors with chisel shaped edges and growing from persistent pulps" (Figs. 1-2)

Eruption of the incisors and formation of dentine occur simultaneously and continuously throughout the animal's life. This growth is normally counterbalanced by mechanical attrition at the incisal edges (Weinreb, Vassil & Michalek 1967).

The upper incisor has been described as a 210° segment of a logarithmic spiral with a lateral shear (Schour & Massler 1962) but also as a segment of a circle about 210° at 5 months of age (Addison & Appleton 1915). The length of the upper incisor along the outer convex side at 5 months of age (Addison & Appleton 1915) is 23.3 mm, the extra alveolar length 8.7 mm.

The main part of the rat incisor consists of dentine. The labial aspect and part of the lateral and medial aspects are covered with a layer of enamel, the rest with a thin layer of cement (Figs. 2-3).

The longitudinal or "extrinsic" growth of the incisor can be measured either as eruption rate or as attrition rate (Sessle 1966; Weinreb et al. 1967). Sessle found these values to be close to each other in the lower incisors. In the upper incisors the situation is similar. Thus according to Addison & Appleton (1915) the rate of attrition is 2.2 mm/week. Similar figures have been given by Schour & Massler (1962) and Stubbs & Knothe (1965) for the rate of eruption.

Fig. 3 Schematic drawing of transverse section of an incisor

Dentine

Dentine is formed by odontoblasts lining the pulp cavity (Figs 2—3) and giving off cell processes extending through the dentine tubules. Owing to the continuous eruption of the tooth the odontoblasts move towards the incisal edge at the same time as dentine formation continues (Schour & Massler 1962). During this process the layer of dentine grows thicker and the pulp space consequently narrower.

The first stage in dentine formation consists of the formation of an organic matrix which later becomes calcified (Erdheim 1911; Schour & Massler 1962; Bevilander & Nakahara 1966; Symons 1967). As in the osteon, the mineralisation does not follow immediately after the formation of the matrix but a zone of uncalcified tissue, the predentine, normally exists like the osteoid (Frost & Villanueva 1960a).

Besides collagen, the main organic constituent (Stick 1966; Brattstrom & Burnett 1966; Piez & Ikin 1960; Lastor 1964, 1967) and small amounts of other proteins, the matrix contains mucopolysaccharides, lipids, citrate and lactate (Stick 1966; Lastor 1967).

The mineral of dentine — like that of other mammalian hard tissues — consists mainly of an apatite. In normal dentine there is probably only one crystalline phase with a structure resembling that of hydroxyapatite (Carlstrom 1966; Jenkins 1966; Trautz 1966, 1967).

Further studies on the rate of apposition of rat incisor dentine

In 1921 Marshall stated "The interstitial growth of the dentine of the persistent teeth of the rat is shown by azo dyes under the microscope amounts approximately to 0.01 mm per day."

Schour and co-workers have performed several studies on the rate of dentine apposition using sodium fluoride or alizarine red S as intravital markers or calculating the rate during known time periods of experimental interferences. They claim the daily rate of apposition of dentine in the white rat's incisors from 40 days of age onwards to be very close to 16 μ m (Schour & Smith 1934, 1936; Schour & Stedman

1935 Schour 1936 Schour & Hoffman 1935 1937 1939 a and b Schour & Missler 1962) During the early life of the animals the rate is somewhat higher (Herzberg & Schour 1941)

Wattam (1942) measured the rate of apposition of dentine in the upper incisors of the white rat after injection of alizarine red S and strontium chloride The values given for the daily appositional rate deviated only moderately from the 16 μm given by Schour and co-workers except one value where the rate is given as 9.5 μm Differences in the rate after injections of alizarine red S and strontium chloride were found and were attributed to a difference in toxicity of the two substances the former substance being the more toxic one

In an extensive survey of dentinogenesis Symons (1967) refers to Schour and co-workers and states 'In the rodent incisor the 16 μm increments represents the amount of dentine laid down and calcified daily'

BONE

The periosteal and endosteal formation of new bone in the shafts of long bones occurs by appositional growth on existing surfaces and is a comparatively simple process Concentric layers of new bone form and the process can be compared to the formation of annual rings in a tree (Frost Roth Villanueva & Stanisavljevic 1961 Sissons 1961 Vanderhoeft Kelly & Peterson 1962)

INTRAVITAL MARKERS IN THE STUDY OF RATE OF APPositionAL GROWTH OF DENTINE AND BONE

Vital dyes and radioactive isotopes have been widely used as markers in calcified tissue research. John Belchier (1736) who found that the bones of pigs fed madder root stained red, also noticed that the teeth were stained.

Administration of an appropriate marker at suitable intervals results in the development of bands visible microscopically in histologic sections. If the time intervals are known and the distances between the bands measured, the rate of formation of tissue can be expressed as a linear measure per unit of time.

For a marker to be acceptable for the present investigation it should produce bands not only in growing dentine but also simultaneously in growing lamellar bone. Perusal of the literature in the search for a suitable marker revealed that in the rat the appositional growth of dentine had been studied with the aid of different markers. Marshall (1921) tried several vital dyes including alizarine. Pfluger (1931) used uranoporphyrin. Alizarine red S (Schour & Hoffman 1939 b; Weinmann 1942; Johannessen 1961), strontium chloride (Weinmann 1942), sodium fluoride (Schour & Hoffman 1939 b) and chlorazol fast pink B (Johannessen 1961) have also been used.

Several of the dyes used by Marshall (1921) did not stain satisfactorily. The staining properties of alizarine were satisfactory but the use of this dye affected the weight gain of the animals. Also Weinmann (1942) found that alizarine had toxic effects. Studying bone formation Harris (1960) and Harris, Travis, Iriber, & Radin (1964) observed a toxic effect of alizarine red S. Of the other markers mentioned sodium fluoride and strontium chloride are known to interfere with mineralisation (Schour & Smith 1935; Weinmann 1942; Pindborg

1935 Schour 1936 Schour & Hoffman 1935 1937 1939 a and b Schour & Missler 1962) During the early life of the animals the rate is somewhat higher (Herzberg & Schour 1941)

Winnmann (1942) measured the rate of apposition of dentine in the upper incisors of the white rat after injection of thiazine red S and strontium chloride The values given for the daily appositional rate deviated only moderately from the 16 μm given by Schour and co-workers except one value, where the rate is given as 9.7 μm Differences in the rate after injections of thiazine red S and strontium chloride were found and were attributed to a difference in toxicity of the two substances the former substance being the more toxic one

In an extensive survey of dentinogenesis Symons (1967) refers to Schour and co-workers and states In the rodent incisor the 16 μm increments represents the amount of dentine laid down and calcified daily

BONE

The periosteal and endosteal formation of new bone in the shafts of long bones occurs by appositional growth on existing surfaces and is a comparatively simple process Concentric layers of new bone form and the process can be compared to the formation of annual rings in a tree (Frost Roth Villanueva & Stanisavljevic 1961 Sissons 1961 Vanderhoeft Kelly & Peterson 1962)

INTRAVITAL MARKERS IN THE STUDY OF RATE OF APPositionAL GROWTH OF DENTIN AND BONE

Vital dyes and radioactive isotopes have been widely used as markers in calcified tissue research. John Belchier (1736) who found that the bones of pigs fed madder root stained red, also noticed that the teeth were stained.

Administration of an appropriate marker at suitable intervals results in the development of bands visible microscopically in histologic sections. If the time intervals are known and the distances between the bands measured, the rate of formation of tissue can be expressed as a linear measure per unit of time.

For a marker to be acceptable for the present investigation it should produce bands not only in growing dentine but also simultaneously in growing lamellar bone. A survey of the literature in the search for a suitable marker revealed that in the rat the appositional growth of dentine had been studied with the aid of different markers. Marshall (1921) tried several vital dyes including alizarine. Pfluger (1931) used uroporphyrin. Alizarine red S (Schour & Hoffman 1939b, Weinmann 1942, Johannessen 1961), strontium chloride (Weinmann 1942), sodium fluoride (Schour & Hoffman 1939b) and chlorazol fast pink B (Johannessen 1961) have also been used.

Several of the dyes used by Marshall (1921) did not stain satisfactorily. The staining properties of alizarine were satisfactory but the use of this dye affected the weight gain of the animals. Also Weinmann (1942) found that alizarine had toxic effects. Studying bone formation Harris (1960) and Harris, Travis, Friberg & Radin (1964) observed a toxic effect of alizarine red S. Of the other markers mentioned sodium fluoride and strontium chloride are known to interfere with mineralisation (Schour & Smith 1933, Weinmann 1942, Pindborg

1950 Yager Hinrichsen & Cohen 1964 Yager 1966) and chlorazol fast pink B with the weight gain of the animals (Johannessen 1964) Uroporphyrin seemed to be less readily available.

It was soon realised that it was among the tetracyclines that the marking agent was to be sought. The staining properties of the tetracyclines were initially observed simultaneously in the skeleton and in the teeth (Andre 1956 Rill 1961 Kelly 1957 Milch Rill & Tobie 1957 1958) where they are deposited in the enamel and dentine undergoing calcification at the time of administration of the marker and form a compound with yellowish fluorescence in UV light (Zipkin & Larson 1960 Bevelander Rolfe & Cohn 1961 Boyne & Miller 1961 Owen 1961 Owen Stevenson & Keith 1962 Hultth & Olerud 1962 Harcourt 1963 Storey 1963 Yager Hinrichsen & Cohen 1964 Bevelander 1964 Bennett & Iraw 1965 Bevelander & Nishitani 1965 Tofgren Nylén & Omnell 1965 Zistav Malck Zik & Kolt 1966 Zussman 1966 Bennett 1967).

They accumulate also in bone where mineralisation is active (Ghossein 1959 Harris Jackson & Lowsey 1962 Urist & Ibsen 1963) and form a compound fluorescing in UV light.

They are bound to the mineral and possibly also to the matrix (Steendijk 1964 Bevelander & Nishitani 1965). It has been suggested that calcium salt reacts more readily in the initial stage of formation of apatite than later (Urist & Ibsen 1963).

The potential value of the tetracyclines in studies of the rate of dentine formation has been realised but not exploited by Gron & Johannessen (1961) and Hultth & Olerud (1962).

In skeletal tissues the tetracyclines have been used in studies of bone grafts (Purman 1966) immature bone formation (Harris 1960 Vanderhoeft Kelly & Peterson 1962 Frost 1960 1962 Frost Roth Villmueva & Stanisavljevic 1961 Frost & Villmueva 1960 Frost Villmueva & Roth 1960 Frost Villmueva Roth & Stanisavljevic 1961 Hultth & Olerud 1962 Stanisavljevic Roth Villmueva & Frost 1962 Holmes 1963 Lee 1963 1964 Linderos & Frost 1961 Lindry & Hirsch 1961 Tapp 1966) endochondral calcification and bone formation (Hultth & Olerud 1962 Hansson 1964 1967 Tapp 1966 Sundén 1967) and cell formation (Milch et al 1958 Urist & Ibsen 1963 Hultth & Olerud 1961).

Tetracyclines may have certain side effects such as discoloration of the teeth in children and enamel hypoplasia (Schwartzman & Schuster 1956 Schwartzman Edelick Kukrzycki & Foley 1958 Wallman & Hilton 1962 Hamp 1967) inhibition of calcification in enamel and dentine in

the rat incisor (Bevelander et al 1961) retardation in development of the skeletal system in the chick embryo (Bevelander Aikawa & Rolle 1960) disturbed mineralisation in tissue cultures of embryonic mice bone (Saxen 1967 1966) retardation of skeletal growth in the dog (Owen 1963) and disturbed endochondral bone growth in the rabbit (Hansson 1967).

The disturbances of tooth development vary with the type of tetracycline used and the dose given and probably also with the route of administration. For children Wulmar & Hilton (1962) believed oxytetracycline to be less toxic than tetracycline. This opinion is shared by Kienitz (1964). Studying the effect on enamel of rat incisors Omnell Iöfgren & Nylén (1966) and Iöfgren Omnell & Nylén (1968) found oxytetracycline to produce less severe disturbances than tetracycline hydrochloride.

In the incisors of the rat Antlovski & Krilovic (1966) found a hypomineralised band in the dentine after having fed the animals a diet containing tetracycline hydrochloride. The daily dose was about 13 mg/kg bodyweight. Gron & Johannessen (1961) found that a dose of oxytetracycline of 30 mg/kg bodyweight did not produce any micro-radiographically demonstrable hypomineralisation in dentine in the molars of the white rat. In dogs even considerably larger doses (Owen 1963) had no effect on the degree of mineralisation of the dentine as visualised with microradiography.

Even if the degree of mineralisation may be affected it does not necessarily follow that also the rate of matrix formation will be impaired. Information on this point is rather scanty. A search of available literature failed to reveal a comparative study of the rate of appositional growth of bone or teeth measured by tetracycline marking and by some other method. Neither could any study be traced of the role of such appositional growth after different doses of tetracycline.

Gablin Bevelander & Tramsie (1963) found the growth in length of the fibula in premature infants to be decreased during the administration of tetracycline. Liu O'Hara & Keidel (1964) could not find any disturbances of the growth process in the fibula but they used oxytetracycline and in smaller doses. The mode of administration was also different. Owen (1963) gave large doses of tetracycline chlorotetracycline and oxytetracycline daily to young dogs for 4 weeks. He found retardation of bodyweight increase and longitudinal growth of radius and femur only after the administration of chlorotetracycline. This retardation ceased on withdrawal of the agent and was followed by

rapid growth. Hansson (1967) considered oxytetracycline to be the least toxic of the tetracyclines and used it in his study of endochondral bone growth. Oxytetracycline was also used by Sundén (1967) in a similar investigation. These investigators used rabbits as experimental animals and gave 1 mg oxytetracycline/kg body weight. In an investigation of the growth in length of the tibia in young rats Tapp (1966) used tetracycline in a dose of 75 mg/kg body weight. He compared the results obtained with the tetracycline method with those obtained with a radiological method and found a disparity. The tetracycline method was considered more accurate. The possibility of a toxic effect of tetracycline was not discussed.

When the tetracyclines have been used as markers in lamellar bone fairly large doses have been given. In a survey "Tetracycline bone labeling" Frost et al (1961) say "About 75 milligrams per kilo in animals is adequate." The dosage of chlortetracycline to dogs employed by Lee (1964) varied between 20 and 50 mg/kg body weight intravenously. Tapp (1966) gave 75 mg tetracycline/kg body weight to rats.

In a survey of "The effect of tetracycline on mineralization and growth" Bevelander (1964) concludes "absence of adverse side effects when trace amounts are administered." However, he did not state what could be considered as traces.

Summarising, the use of oxytetracycline in small doses carries at most a small risk of interfering with mineralization and/or appositional growth of dentine and lamellar bone. It was therefore decided to use this marker in the present investigation.

BRIEF SURVEY OF EFFECTS OF PITUITARY GROWTH HORMONE OR HYDROCORTISONE ON DENTINE AND BONE

INTRODUCTION

In the investigation of the possibility to influence the rate of apposition of dentine it was decided to use 2 agents: one expected to accelerate dentine formation and one expected to retard it. The growth hormone and hydrocortisone were selected (see below).

The following survey of the effects of the hormones is extended to comprise the effects observed in dental and skeletal tissues not only in some experimental animals but for comparison also in man.

PITUITARY GROWTH HORMONE

Pituitary growth hormone (GH) is a protein and has been extracted from the hypophysis of various animals. Extensive surveys of the chemistry and physiology of growth hormone have been given by Knobil & Hotchkiss (1964), Matsuzaki & Raben (1965) and Evans, Briggs & Dixon (1966). A species specificity exists in man only. GH from man and monkeys is said to have any effect while the rat responds to GH from several species (Papkoff & Li 1962; Raben 1962: 1).

It is an anabolic agent and promotes the growth of most tissues. In man and experimental animals GH has been found to promote nitrogen retention (Birtlett 1955; Russell 1955; Shorr, Carter, Smith Jr, Kennedy, Bavel, Roberts, Sonkin & Livingstone 1955; Beck, McGarry, Dyrnsfurth & Venning 1959; Bergenstal & Lipsell 1960; Henneman, Forbes, Moldawer, Dempsey & Carroll 1960). In mineral metabolism retention of calcium, phosphorus, sodium and potassium has been reported (Shorr et al 1955; Beck et al 1958; Raben 1962: 7). However, it is the opposite effect on the calcium balance that has been observed

rapid growth. Hansson (1967) considered oxytetracycline to be the least toxic of the tetracyclines and used it in his study of endochondral bone growth. Oxytetracycline was also used by Sundén (1967) in a similar investigation. These investigators used rabbits as experimental animals and gave 1 mg oxytetracycline/kg bodyweight. In an investigation of the growth in length of the tibia in young rats Tipp (1966) used tetracycline in a dose of 75 mg/kg bodyweight. He compared the results obtained with the tetracycline method with those obtained with a radiological method and found a disparity. The tetracycline method was considered more accurate. The possibility of a toxic effect of tetracycline was not discussed.

When the tetracyclines have been used as markers in lamellar bone fairly large doses have been given. In a survey Tetracycline bone labeling Frost et al (1961) say. About 75 milligrams per kilo in animals is adequate. The dosage of chlortetracycline to dogs employed by Lee (1964) varied between 20 and 50 mg/kg bodyweight intravenously. Tipp (1966) gave 75 mg tetracycline/kg bodyweight to rats.

In a survey of The effect of tetracycline on mineralization and growth Bevelander (1964) concludes absence of adverse side effects when trace amounts are administered. However he did not state what could be considered as traces.

Summarising the use of oxytetracycline in small doses carries at most a small risk of interfering with mineralisation and/or appositional growth of dentine and lamellar bone. It was therefore decided to use this marker in the present investigation.

BRIEF SURVEY OF EFFECTS OF PITUITARY GROWTH HORMONE OR HYDROCORTISONE ON DENTINE AND BONE

INTRODUCTION

In the investigation of the possibility to influence the rate of apposition of dentine it was decided to use 2 agents - one expected to accelerate dentine formation and one expected to retard it. The growth hormone and hydrocortisone were selected (see below).

The following survey of the effects of the hormones is extended to comprise the effects observed in dental and skeletal tissues not only in some experimental animals but for comparison also in man.

PITUITARY GROWTH HORMONE

Pituitary growth hormone (GH) is a protein and has been extracted from the hypophysis of various animals. Extensive surveys of the chemistry and physiology of growth hormone have been given by Knobil & Hotchkiss (1964), Matsuzaki & Raben (1965) and Evans, Briggs & Dixon (1966). A species specificity exists in man only GH from man and monkeys is said to have any effect while the rat responds to GH from several species (Papkoff & Li 1962, Raben 1962a).

It is an anabolic agent and promotes the growth of most tissues. In man and experimental animals GH has been found to promote nitrogen retention (Bartlett 1955, Russell 1955, Shorr, Carter, Smith Jr, Kennedy, Havel, Roberts, Sonkin & Livingston 1955, Beck, McGarry, Dyrenfurth & Venning 1958, Bergenstal & Lipsell 1960, Henneman, Forbes, Moldaver, Dempsey & Carroll 1960). In mineral metabolism retention of calcium, phosphorus, sodium and potassium has been reported (Shorr et al 1955, Beck et al 1958, Raben 1962a). However, also the opposite effect on the calcium balance has been observed.

(Knobell & Hotchkiss 1964) GH also influences fat and carbohydrate metabolism (Campbell 1955, Greenbaum 1955 Shorr et al 1955 Henneman & Henneman 1960 Raben 1962 a)

In hypopituitarism in man dental development is retarded while in acromegaly and gigantism the excessive production of the growth hormone can lead to overgrowth of the mandible supra eruption of teeth and increased size of dental arch (Schour & Massler 1943 a Gann Lewis & Blizzard 1965, Jenkins 1966)

The effects of GH on rat incisors seem to have received comparatively little attention Schour & van Dyke (1932 a) and Schour (1934 a) found severe changes in the incisors of the hypophysectomised white rat. The eruption was poor the teeth were distorted and abnormally small. After the administration of the growth promoting hormone of the pituitary the eruption rate of the incisor increased but the histological alterations were not significantly influenced (Schour & van Dyke 1932 b Schour 1934 b) Brume Becks Ray & Evans (1954) found hypophysectomy to cause a rapid decrease in the eruption rate of the upper incisors in the rat. Dentinogenesis was affected but less severely than amelogenesis. They also described folding of the incisors and diminished pulp space findings which have also been made by other investigators (Becks Collins Simpson & Evans 1946 Christensen & Pindborg 1950)

In normal animals the administration of growth promoting hormone did not alter the eruption rate but increased bodyweight (Schour & van Dyke 1932 b Schour 1934 b) Becks Collins Asling Simpson Li & Evans (1948) treated normal female rats for several months with growth hormone. They found increased activity of the odontoblasts and ameloblasts in the incisors. No change of eruption rate was found. Brume Becks & Evans (1954) found administration of growth hormone to normal adult female rats to have no effect on the rate of incisor eruption but the teeth increased in size. None of the above mentioned investigators carried out any studies on the rate of apposition of dentine.

Asling & Evans (1961) have surveyed the regulation of skeletal development by the anterior pituitary. Their account is based chiefly on data from the rat. Pituitary dwarfism and short stature in man have been successfully treated with GH (Raben 1962 b Tanner & Whitehouse 1967). The effect of GH on skeletal tissue in human acromegaly is well known. Growth hormone normalises skeletal development in hypophysectomised rats and causes overgrowth in normal rats (Evans Becks Asling Simpson & Li 1948 Asling Simpson Moon Li & Evans 1955 Asling Simpson & Evans 1962). The tibial test is a bioassay for

GH which increases the epiphyseal width in hypophysectomised female rats (Evans Simpson Marx & Librick 1943 Greenspan Li Simpson & Evans 1949 Geschwind & Li 1955)

Koskinen (1959 1963) claimed GH to accelerate fracture healing in man and in the rat

HYDROCORTISONE

Cortisone and hydrocortisone (cortisol) are glucocorticoids and have a catabolic effect (Ashmore & Morgan 1967) The effects they produce on systemic administration are similar (Asboe Hansen 1958)

In the rat Schour & Ross (1936) found the calcification of dentine to be disturbed after adrenalectomy

Goldsmith & Ross (1953) gave cortisone to pregnant rats and found "accelerated differentiation and organization" of the odontoblastic layer in the lower incisors of the offspring They also discovered signs of increased deposition of dentine Administration of cortisone retards dentinogenesis in the molars of white rats (Johannessen 1964)

In children with Cushing's syndrome (Liddle 1967) and after the administration of corticosteroids (Friedman & Strain 1966) growth is decreased The osteoporosis occurring in Cushing's syndrome and after therapeutic administration of the hormones is known (Isaksson & Lindholm 1965 Klein Villanueva & Frost 1965 Collins 1966) The healing of fractures is said to be retarded in patients with Cushing's syndrome (Asboe Hansen 1958)

Similar findings have been made in experimental animals after the administration of glucocorticoids *vi* retarded growth in young rats (Sissons & Hadfield 1955 Storey 1960 Alabourn Dikstein Zor & Sulman 1966) retarded formation of lamellar bone in the rat (Stanisavljevic Roth Villanueva & Frost 1962) and impaired bone repair in the rat (Duthie & Baker 1955 Koskinen 1959 Storey 1960 Hulth & Olerud 1964) and the rabbit (Rogin Howes Plotz Meyer Blunt & Little 1950 Gothman 1961)

AUTHOR'S INVESTIGATION

MATERIAL AND METHODS

ANIMALS

Sprague Dawley rats were used. It was initially intended to breed all the animals at the experimental unit in order to know their ages with a high degree of accuracy. However, it was discovered that the weights of such animals at 10 months of age were lower than expected from the normal weight curve for animals from a breeding centre. From then on adult animals were purchased from a breeding centre. When young animals were required, pregnant rats were bought and their young were used when they had reached desired age.

After arrival the animals were observed for at least a week before being used in the experiments. The same room was used for all experimental categories. Cycling of light and darkness was achieved by artificial light. The mean temperature ranged from about 24°C as measured during 5 days in February to about 26°C as measured during 5 days in July. The relative humidity was slightly below 40 per cent. Only minor variation of the temperature and humidity was found during an uninterrupted 48 hour control period. The animals were kept in the same type of cages and fed the same diet (pellets and water *ad libitum*) as in the breeding centre. The pregnant and lactating animals were given a special type of food. During the experiments the animals were weighed at regular intervals.

Of the 271 animals used in the experiments proper, only one died.

VITAL MARKING

Oxytetracycline (OTC) was used (Terramycin® Pfizer). The stock solution contained 50 mg OTC per ml and was diluted in physiologic saline before use.

injections were given on days No 0 8 12 20 and 24. These intervals were chosen because it was initially thought advisable to use periods that were multiples of each other. Preliminary experiments had also shown that when the experimental period was about 3—4 weeks the pattern of growth of the dentine during this period could be traced in about half of the number of histologic sections to be taken from the tooth. (In some experiments [page 76] OTC was given at 6 day intervals.)

Young animals received 0.5 mg (vol 0.5 ml) and adult animals 2 mg (vol 1 ml) OTC at each injection. This means that the dose given to normal animals never exceeded 10 mg OTC/kg bodyweight. In each experimental category the OTC was injected at the same time of day.

Four days after the last injection of OTC the animals were sacrificed (on day 28) by ether. The upper incisors and femur and tibia on both sides were removed either immediately or after storage of the cadavers in the deep freeze. The bones were afterwards placed or replaced in the deep freeze for later investigation. The choice of a 4 day interval between the last injection of OTC and sacrifice was based on the assumption that apposition of dentine during this interval could be measured and included in the investigation and on the fact that measurement to the innermost fluorescent band was easier when it was not situated too close to the dentine border.

HISTOLOGIC TECHNIQUE

After fixation in 70 per cent ethyl alcohol for at least 24 hours the teeth were embedded in Ward's Bioplastic.

In preliminary experiments both longitudinal and transverse sections were prepared. However as a rule longitudinal sections permitted only measurement of distances between fluorescent bands in the middle part of the tooth. The fluorescent bands in the apical and incisal ends were not always well defined which made it impossible to measure the distances between them with acceptable precision. This haziness of the bands was thought to be due to technical difficulties in the preparation of the sections which were in turn at least partly ascribable to the spiral shape of the tooth. Nor did they allow examination around the whole periphery of the tooth. Transverse sections proved easier to prepare and to be more informative.

The plastic blocks were ground until the contours of the tooth viewed from the side were clearly visible through a thin layer of the embedding material. The planes in which the transverse sections were to be

Fig. 4 Part of transverse section showing 4 fluorescent bands. The 3 located close to each other produced by intraperitoneal injections of OTC and the single more central one by an intravenous injection. The drawing shows position of photographed part in the transverse section. About 10 mg OTC/kg bodyweight. Adult female rat 66>

Before deciding upon the route of administration the fluorescent bands produced by intraperitoneal and intravenous (into a tail vein) injections were compared in respect of clearness. Five adult female rats were given 3 consecutive intraperitoneal injections of OTC (about 10 mg/kg bodyweight) at intervals of approximately 24 hours. Eight days after the last of these injections the animals were etherised, the femoral vein was surgically exposed and the same dose of OTC was injected into it. No appreciable difference was found between the clearness of the first 3 fluorescent bands and that of the fourth (Fig. 1). Being technically simpler the intraperitoneal route was therefore chosen for the administration of OTC.

Oxytetracycline was given at intervals of 8, 4, 8 and 4 days i.e. the

of radiation was an Osram super pressure mercury lamp HBO 200 W. The primary filters were BG 38/2 and BG 12/4 allowing transmission of light with a wavelength between 3300 and 5000 Å. As a secondary filter a barrier filter 50 (Schott) was used. An ocular (Kpl 12.5X) was equipped with a 10 mm micrometer divided into 100 parts. The objective was planachromatic 10X (NA 0.22) magnification.

placed were determined in the following way: the mid point of an imaginary line connecting the apex and the incisal edge was determined and a line was drawn at right angle to it. The 2 right angles thus formed were divided into 2 equal parts. Each of these 4 parts was then likewise divided into 2 equal parts. These radial lines were marked on the block (Fig. 5a). The marking was facilitated by the use of a glass plate with engraved lines.

Segments of the tooth (Fig. 5b) were cut with a circular saw and ground manually to a thickness of approximately 70–100 μ m. The grinding technique was essentially that described by Irost (1958) for bone. Each section was placed dry on slide and covered with a cover glass.

MEASURING TECHNIQUE

A conventional binocular microscope (Zeiss Oberkochen) equipped with an accessory for fluorescence microscopy was used. The source

tion. The calibration was made so that each part (unit) in the ocular micrometer corresponded to 10 μ m.

Distances between consecutive fluorescent bands as measured in the direction of the dentinal tubules (Fig. 6) were determined at points numbered 1—10 (Fig. 7). The bands were numbered 1 to 5 (Fig. 7).

Measuring was started at point 1 and continued around the section. Measuring points 1, 2, 3 and 7 were fairly easy to identify. Points 4, 5, 6 and 8, 9, 10 were distributed evenly along the lateral and medial aspects. At point 2 the thickness of the entire dentine layer, from the dento-enamel junction to the pulp (=DL pulp distance=height of the dentine layer), was measured.

The fluorescent bands were usually well defined. Attempts were always made to measure the distance between the peripheral borders of consecutive fluorescent bands; this part of the bands forming first. As a rule the positioning of the eyepiece was not difficult except in some areas where the tubules were slightly curved and an approximation had to be made (Fig. 6). In the sections situated nearest the mesial edge bands 4 and 5 were sometimes very close to each other. At points 1 and 3 they could sometimes not be distinguished from one another and then the distance between them was said to be 0. The distances found between bands at various points were entered in separate record sheets, one for each section.

PRELIMINARY ANALYSIS OF THE MEASURING METHOD

It soon became obvious that the technical measuring difficulties varied with the location of the section. It was also more difficult to measure the distance between a fluorescent band and the pulp outline than between 2 fluorescent bands.

To test the precision of the measuring technique a number of sections from animals used only for preliminary investigation were measured by the author and by a specially trained assistant. Distances between 2 consecutive fluorescent bands and between a band and the outline of the pulp chamber were measured. The sections used allowed measurement at every point from 1 to 10. Each distance was measured twice. The author performed 3520 and the technical assistant 3920 measurements.

Owing to the construction of the measuring device over or under measurement of the distance by one major grade (5 measuring units) occasionally occurred. Therefore as a precaution when a difference

of at least 4 units was found between double determinations: a third measurement was made and then those 2 of 3 measurements that appeared most correct were used.

Analysis showed that the distance between a fluorescent band and the pulp chamber was more difficult to measure. This was exemplified by the residual standard deviation which was approximately 50 per cent higher in spite of the above mentioned procedure with a third measurement. This distance was therefore not used separately in the subsequent investigations.

Concerning the distance between 2 consecutive fluorescent bands on the basis of 38 sections measured by the author and 39 sections measured by the technical assistant it was found that the reproducibility of double determinations in sections 1—4 was similar and for these taken together. For the author it was 0.56 ± 0.18 and for the technical assistant 0.69 ± 0.17 . The corresponding figures for section 5 were 0.73 ± 0.10 and 0.72 ± 0.21 respectively. Tabulation and a rough comparison showed that the measurements could be made with approximately the same precision at all points. No significant difference was found between the absolute values noted by the 2 examiners.

In the actual experiments measurements were made by the technical assistant and by the author and each distance was measured on 2 days. The measurements made by the assistant were controlled by the author in randomly selected sections.

PREPARATION FOR STATISTICAL ANALYSIS

The continuous eruption of the incisors prevented the occurrence of 5 fluorescent bands in all sections 0 to 6. A loss of material occurred because of "missing bands". Some injections of OTC resulted in the appearance of only faint bands or no bands at all. Finally, some sections were torn or damaged during preparation. Thus the vast material available was not complete in every respect but had to be surveyed and arranged to provide maximal information. To facilitate the understanding of what follows it might be convenient here to give a list of certain definitions.

Section designates each of the transverse regularly spaced histological sections of the incisor and are numbered 0 to 6 inclusive according to their distance from the apex (Figs 5 a and b).

Band A fluorescent band resulting from administration of OTC. The band produced by the first administration of OTC is given the

tion. The calibration was made so that each part (unit) in the ocular micrometer corresponded to 10 μm .

Distances between consecutive fluorescent bands as measured in the direction of the dentinal tubules (Fig. 6) were determined at points numbered 1—10 (Fig. 7). The bands were numbered 1 to 5 (Fig. 7).

Measuring was started at point 1 and continued around the section. Measuring points 1, 2, 3 and 7 were fairly easy to identify. Points 4, 5, 6 and 8, 9, 10 were distributed evenly along the lateral and medial aspects. At point 2 the thickness of the entire dentine layer from the dento-enamel junction to the pulp (=DL pulp distance=height of the dentine layer) was measured.

The fluorescent bands were usually well defined. Attempts were always made to measure the distance between the peripheral borders of consecutive fluorescent bands, thus part of the bands forming first. As a rule the positioning of the eyepiece was not difficult except in some areas where the tubules were slightly curved and an approximation had to be made (Fig. 6). In the sections situated nearest the incisal edge bands 4 and 5 were sometimes very close to each other. At points 1 and 3 they could sometimes not be distinguished from one another and then the distance between them was said to be 0. The distances found between bands at various points were entered in separate record sheets, one for each section.

PRELIMINARY ANALYSIS OF THE MEASURING METHOD

It soon became obvious that the technical measuring difficulties varied with the location of the section. It was also more difficult to measure the distance between a fluorescent band and the pulp outline than between 2 fluorescent bands.

To test the precision of the measuring technique a number of sections from animals used only for preliminary investigation were measured by the author and by a specially trained assistant. Distances between 2 consecutive fluorescent bands and between a band and the outline of the pulp chamber were measured. The sections used allowed measurement at every point from 1 to 10. Each distance was measured twice. The author performed 3520 and the technical assistant 3920 measurements.

Owing to the construction of the measuring device over or under measurement of the distance by one major grade (5 measuring units) occasionally occurred. Therefore as a precaution when a difference

in each of 3 sections from the middle of the tooth towards the incisal edge

As to the young rats the distances between bands 3—4 and 4—5 were investigated in sections 3 to 6 inclusive and from 2 to 6 respectively. Only in sections 5 and 6 were all 4 distances regularly represented in these young animals

Hereinafter these sets will be referred to as 3—4 4—5 3 4 5 and 6 with above mentioned meanings for adult and young animals. These sets were used whether the statistical calculations were made on the basis of observations at all 10 measuring points taken together or at a single measuring point. In this system section 0 is of no use. Section 6 is useful only when investigating young animals. It was studied in a few adult animals but at this level apposition of dentine seemed to have stopped almost completely and measurement of distances between the inner bands was very difficult or impossible. When section 7 was located too far incisally the same difficulties were encountered.

When double determinations of the distances had been made the material was surveyed and divided into the above mentioned sets right and left side separately. Then the 2 observations in each set were compared. If the difference between the 2 determinations was 4 (measuring) units or more the distance was measured a third time and those 2 that appeared to be most correct were used. In an experimental series 5 sets were made for the right tooth and 5 for the left in adult animals and 4 in young animals. When the analysis was made on the basis of all 10 measuring points taken together 50 measured values (100 with the second determination) were necessary when set 4—5 was to be investigated it was 40 (80) for the other sets from right and left tooth in each animal. If one or more values for a given tooth was missing the tooth could not be included in this analysis. When the individual measuring points were investigated the demands were not so high and consequently more material could be used.

STATISTICAL METHODS

Owing to the large number of data to be handled the statistical analysis was made with a computer. This required the transfer of the values to punched cards. In one of the computer programs selected only one value could be registered on each card. In each card entries were made not only of the value measured but also of the total height of the dentine layer at point 2 and an identification code com

number 5 and is situated nearest the pulp the one produced by the first injection being situated nearest the periphery and is given the number 1. The bands in between are numbered 2, 3 and 4 (Fig. 7).

Interval refers to time. Interval 1 is the period between the 2 first injections of OTC i.e. those injections resulting in bands 1 and 2. *Interval 2 is the period between the second and third injections of OTC resulting in fluorescent bands 2 and 3. Accordingly interval 3 is the period between the third and fourth injections of OTC (bands 3 and 4) and interval 4 the period between the fourth and fifth injections of OTC (bands 4 and 5).*

Distances are to be understood as the distances along the dentinal tubules between fluorescent bands at different points. These distances are the linear measures of the amount of dentine formed during a given period. This measure is given in measuring units (1 unit = 10 μ m) throughout the investigation and called measured value, value measured or observation.

Measuring points are the places on the periphery of the tooth (Fig. 7) which were selected for measurement of distances between fluorescent bands along the dentine tubules.

Set. To obtain a picture of the pattern of dentine apposition from different points of view the observations were arranged in certain combinations and such a combination is called a set.

The purpose of the arrangement of observations into sets was to find out whether and if so how the rate of apposition of dentine varied within a certain period between the sections and — in a single section — how the rate of apposition varied during different intervals.

The distances between bands 1—2 and 2—3 were regularly found only in sections 3, 4 and 5. It was thought that this number of sections was not large enough to allow satisfactory statistical analysis. The following sets were found suitable:

The distances between bands 3 and 4 were found to occur rather regularly from section 2 to 5 inclusive. It seemed suitable to study apposition during this 8 day interval through 4 sections.

The distances between bands 4 and 5 (14 day interval) were, as a rule, represented in sections 1 to 5 inclusive and provided a set.

The distances between all the 5 bands were rather regularly found in sections 3, 4 and 5 and each of these constituted a set.

Thus the rate of apposition of dentine during an 8 day and a 14 day interval could be investigated in different sections. The rate during different intervals of the entire experimental period could be studied

the possible influence of OTC on the rate of dentine apposition the following experiments were made. Twenty five young animals were divided into 3 groups of 8, 8 and 9 animals and given intraperitoneal injections of OTC 1.0, 10.0 and 20.0 mg/kg body weight respectively. The mean weight of the animals at the beginning of experiment was 140.8 g, at the end 168.3 g with negligible differences between the 3 groups. The rate of apposition at measuring point 2 was studied during an 8 day and a 4 day interval following the injections of OTC. No significant difference in appositional rate was found between the 3 groups. A corresponding experiment was made on 24 adult animals divided into 3 equal groups. Mean weight at beginning of the experiment 260.3 g and at the end 272.4 g with negligible differences between the groups. Neither in this experiment were any significant differences found in appositional rate. The results are based upon 141 observations from 10 animals in the 2 groups given 1.0 mg OTC/kg body weight, 293 observations from 15 animals in the 2 groups given 10.0 mg OTC/kg body weight and 209 observations from 14 animals in the 2 groups given 20.0 mg OTC/kg body weight.

It was also noted that when the lowest dosage (1.0 mg/kg body weight) was employed the bands were fainter and more difficult to recognise and the frequency of missing bands was higher. The dosage of OTC employed for the experiments proper was thought convenient and not to have any appreciable effect on the rate of apposition of dentine.

Technique

In each category the injections were given at the same time of the day with a few minutes deviation.

An intraperitoneal injection of a tetracycline compound will produce a fluorescent mark in calcified tissues within 30 minutes (Mitch et al 1951; Lofgren, Nylen & Omnell 1960). Storey (1963) found tetracycline induced fluorescence in enamel 15 minutes after an intraperitoneal injection and Johnson (1966) found fluorescence at the dentine predentine junction within minutes after the injection but did not say how the injections were given. It may be assumed that the absorption starts very soon after an intraperitoneal deposition, that the accumulation in tissues undergoing calcification follows in close succession and consequently that the marking in the tissue corresponds well to the time of the administration.

prising the number of the measuring point the number of the animal right or left side interval and section. As the intervals were not of equal length distances found for the 4 day intervals in sets 3, 4, 5 and 6 had to be doubled. This was made by a specially designed program. A list of the cards was made.

To study the variations in dentine apposition between animals sections and measuring points and their interactions analysis of covariance was carried out. Program BMD 03V (IBM) analysis of covariance version of Feb. 19, 1964 University of Utah Computer Center was selected. The thickness of the dentine layer was chosen as a covariable to correct for the variation in the locations of the sections and for the possible differences in size of the teeth.

Differences found were said to be

highly significant (***) when $P < 0.001$

significant (**) when $0.001 < P < 0.01$

almost significant (*) when $0.01 < P < 0.05$

The variation in the rate of apposition of dentine was investigated further and described with the aid of program BMD 05R (IBM) polynomial regression version of April 13, 1964 Health Sciences Computing Facility UCLA. Program BMD 05R can dispose of only 500 measured values. This meant that when the 10 measuring points together were the subject of the investigation only 10 (set 4—5) or 12 (the other sets) teeth could be investigated simultaneously. Arbitrarily the first of the 2 available observations was selected for this analysis. For the statistical analyses not performed with the aid of a computer conventional methods were used.

SOURCES OF ERROR

Material

Using rats from an inbred stock standardising their nutritional and environmental conditions and maintaining these as close as possible to earlier conditions helps to keep the animal material uniform. Before and during the experiments weighing and inspection of the animals served as a kind of health control.

The adverse effects of OTC on growth were discussed earlier and it was concluded that in view of the smallness of the doses used in the present investigation such effects were surely minimal. To investigate

is not a perfect semi circle but a 210° segment of a spiral the planes of the sections deviate from the radius except section 3. This deviation was estimated in the following way. It was thought justifiable to disregard the slight spiral form of the upper incisor. Assuming the adult tooth to occupy 210° of a circle the following calculations were made. From the point P a line was drawn in the way illustrated in Fig. 8 where d is the distance between P and the true centre of the circle. For the angle marked 10° this holds $\sin 10^\circ = d/r$. According to the sine theorem for the triangle containing the angle α and $\sin \alpha = r \sin 40^\circ$. The following deduction is made $\sin \alpha = \sin 40^\circ \sin 10^\circ$ $\alpha = 10.55^\circ$. Thus the section cuts the tooth at an angle deviating by 10.55° from the radius and the measured distance will be $l = 1 \cos 10.55^\circ = 0.981$ (Fig. 9). At section 5 where the total height of the dentine layer is roughly 90 units this distance is measured 1.5 units too long. The distances between bands rarely exceed 20 units and then the error (0.34 measuring units) can be ignored.

The sections may be placed apically or incisally to the intended place on the curvature of the tooth. It was thought necessary to compensate for this methodological error. It is obvious that the height of the dentine layer increases towards the incisal edge. For every section the total height of the dentine layer from the dento enamel junction to the pulp was determined at measuring point 2. The distance was measured twice if necessary 3 times. It may seem illogical to use the outline of the pulp chamber as the limit of this distance and not band 5. It having been shown that the distance between a band and

Fig. 8

Fig. 9

Figs. 8 and 9 Drawing showing how deviation of section α from radius is estimated

Not every injection of OTC resulted in a fluorescent band. One explanation may be that OTC was deposited in such a place (possibly in the bowel) that very little or no absorption occurred. If only little absorption occurred the fluorescence could be below the visible limit. If the fluorescence is primarily weak but discernible the small amount of fluorophore might be washed away during the fixation or during the preparation of sections and then the bands will not be visible. A possible source of error was to mistake one missing band for another. For example, to believe that band 4 was missing when in reality it was band 5. The experimental period was then read as 12 days instead of 8. To avoid this every section was controlled by both observers. Otherwise missing bands were not a source of error.

To investigate whether deep freezing might influence the distances measured a group of animals comprising 6 adult and 4 young rats was investigated. The adult rats were given 2 injections of OTC at a 4 day interval the young ones according to the usual scheme. The upper incisors were removed immediately after sacrifice. The right one was placed directly into alcohol for fixation and the left one was deep frozen. After an appropriate period of fixation the right incisor was embedded in plastic. The left one was thawed and frozen again 3 times before it was fixed and embedded. Corresponding distances were measured in ground sections of the right and left tooth. The material comprised 190 pairs (right left) of observations from the adult animals and 100 pairs from the young ones. Sections from 1 to 5 inclusive and all 10 measuring points were represented. Only the first of the double determinations on the right side were compared with those on the left side. The differences between the right and the left teeth were calculated. No significant difference was found between right and left teeth. Normally no significant difference exists between right and left teeth (see page 50). Deep freezing of bone tissue before the preparation of sections for fluorescence microscopy does not diminish the intensity of the fluorescence (Mitch et al 1957, Frost, Roth, Villanueva & Stanisavljevic 1961, Hulth & Olsson 1964). In the present material visual inspection did not reveal any difference in intensity of fluorescence between the left and right teeth.

It is quite clear that the relative crudeness of the method used for determining the positions at which the sections were to be taken implies a fairly large source of error. It is also to be observed that the tooth or a segment of it is not repeatedly divided into 2 equal parts except at the site of section 3 even if the angles are so divided. As the tooth

In what follows apposition of dentine is given in measuring units. If these units were converted to μm it would perhaps give a false impression of accuracy. The precision of the measured values is known but the true value for apposition of dentine is not. When apposition of dentine is later expressed as μm per day this reservation should be borne in mind.

It is possible that the measuring points do not correspond strictly to each other in the different sections. The enamel may perhaps cover a varying part of the circumference of different sections of one and the same tooth and the reference points consequently have a different location. Judging from inspection under the microscope this difference if any was small. It was therefore not considered necessary to investigate this matter separately. It was decided to use the method developed and then find out what the variation could be. It was considered probable that at most a comparatively slight shift could occur between the odontoblasts and the dentine they had formed and into which their cell processes passed.

The third measurement was made because the construction of the measuring device favoured faulty readings of about 5 units. These errors are to be regarded as gross errors. As such an attempt to eliminate them was justifiable (Hallert 1967). To estimate the effect of this attempt on the calculations an analysis was made during the course of the investigation. In the category comprising 16 adult normal animals 1400 measurements were made on teeth from the right side and 1420 on teeth from the left side. The third measurement was made in 16 and 20 cases respectively. In young animals treated with growth hormone 2630 measurements were made on teeth from the right side and the third control made in 24 cases. In the analysis of covariance only the variation within replicates was influenced. Investigation showed that it was about 5 per cent "too low".

Statistical analysis

Every calculation and step in the preparation for statistical analysis was made at least twice and the punching of cards was controlled. The computer programs must be regarded as adequate and the manual calculations made do not argue against this assumption. The covariance proved to be a small source of error in some of the calculations. When investigating the differences between intervals in one section it served the intended purpose. When investigating how a distance varied be

the pulp was more difficult to measure than that between 2 fluorescent brands. It was nevertheless used because it was desired to measure the height of the whole dentine layer. The values were not used directly in the estimation of the rate of apposition of dentine but as a more accurate description of the location of the section than its number. First an attempt was made to define the section with the aid of the DE pulp distance at point 2. As a trial it was simply assumed that section 1 were those whose dentine height at point 2 varied between 25 and 35 μ m. The other sections were assigned to appropriately spaced groups. The method worked fairly well for sections from the apical parts of the teeth but for those from the incisal parts the overlapping between the DE pulp values was pronounced and using this method would have meant an unnecessary loss of material. Instead it was decided to have the DE pulp value as covariable in the statistical analysis this way making a correction.

When these DE pulp observations were taken together and scrutinised it was also possible to check that the sections had not been confused for example section 3 mistaken for section 4. This control was possible because it was known that the DE pulp values should be increasing from section 0 or 1 to 5 and 6 for each tooth.

If one section of a tooth had a high (or low) DE pulp value the other values for the same tooth were as a rule also high (or low). It seemed that if a section *e.g.* the one first cut was placed incisally to the position intended all the others were also placed too near the incisal end and then of course the DE pulp values were higher than they should have been. However it appeared that the spaces between the sections were regular. If the sections were located too far apically the DE pulp values were lower than the average but — as it seemed — still fairly regularly spaced.

Measuring method

Measuring along the dentinal tubules seems convenient as the tubule as described is the path of cellular activity (Herzberg & Schour 1941). It is of course not possible to place the measuring device along a single dentinal tubule. It must however be placed more or less parallel to the striation visible in the histologic sections and produced by dentinal tubules (Fig. 6). Once the measuring device had been placed in position on a section it was not moved until all distances at the point had been measured.

In what follows apposition of dentine is given in measuring units. If these units were converted to μm it would perhaps give a false impression of accuracy. The precision of the measured values is known but the true value for apposition of dentine is not. When apposition of dentine is later expressed as μm per day this reservation should be borne in mind.

It is possible that the measuring points do not correspond strictly to each other in the different sections. The enamel may perhaps cover a varying part of the circumference of different sections of one and the same tooth and the reference points consequently have a different location. Judging from inspection under the microscope this difference if any was small. It was therefore not considered necessary to investigate this matter separately. It was decided to use the method developed and then find out what the variation could be. It was considered probable that at most a comparatively slight shift could occur between the odontoblasts and the dentine they had formed and into which their cell processes passed.

The third measurement was made because the construction of the measuring device favoured faulty readings of about 5 units. These errors are to be regarded as gross errors. As such an attempt to eliminate them was justifiable (Hallert 1967). To estimate the effect of this attempt on the calculations an analysis was made during the course of the investigation. In the category comprising 16 adult normal animals 1400 measurements were made on teeth from the right side and 1420 on teeth from the left side. The third measurement was made in 16 and 20 cases respectively. In young animals treated with growth hormone 2030 measurements were made on teeth from the right side and the third control made in 24 cases. In the analysis of covariance only the variation within replicates was influenced. Investigation showed that it was about 5 per cent "too low".

Statistical analysis

Every calculation and step in the preparation for statistical analysis was made at least twice and the punching of cards was controlled. The computer programs must be regarded as adequate and the manual calculations made do not argue against this assumption. The covariable proved to be a small source of error in some of the calculations. When investigating the differences between intervals in one section it served the intended purpose. When investigating how a distance varied be

tween sections the covariable slightly strengthened the variation. However, analysis showed that when this small error was corrected for there was still a highly significant variation.

The sources of error, some of which were discussed above, contribute to the variation of the observations. Estimates of such variations will be given in subsequent chapters.

NORMAL APPPOSITION OF DENTINE

MATERIAL

Four categories of animals were used

- 1) Adult rats age about 9 months at sacrifice
- 2) Adult rats age exactly 10 months at sacrifice. These animals were reared at the experimental unit and their weights at sacrifice were lower than normal
- 3) Adult rats age about 11 months at sacrifice. They were breeders bought from a breeding centre and their weights at sacrifice were considered normal
- 4) Young rats age 58 days at sacrifice

RESULTS

Adult animals

Age 9 months

Computer analysis Since the most extensive analysis was performed on data about the 9 month old animals this category will be dealt with first. It comprised 20 animals. Three could not be used in the computer analysis because fluorescent band 4 was missing. The number of animals used in the analyses of the different sets are given in the tables or can be obtained by adding 1 to the number of degrees of freedom for factor T (tooth). The mean weights and weight ranges are given in Table 1. As the animals were not numbered until they were sacrificed the weights of the individual animals were not known until then. When the observations had been grouped in the 3 sets covering the 10 measuring points together it was possible to calculate the mean weight for each set right and left side separately. The range of the

Table 1 Mean weights and weight ranges in grams at beginning and end of experiment in different categories of adult female rats

Day	Age at end of experiment	Bodyweight (mean and range) adult animals		
		8 mths	10 mths (low weight)	11 mths (normal weight)
0		272.4 250—295	262.2 240—290	335.6 314—360
24		296.0 270—320	266.1 240—310	334.6 294—368

mean weights in these 10 sets was from 286.1 to 297.1 grams on day No. 28. For teeth from the right side the mean weights of the animals contributing observations to the analysis of each of the 10 points in each of the 5 sets were calculated. The resulting 50 mean weights clustered around the value of 290 grams on day No. 28.

Analysis of covariance was made for the 5 sets, right and left tooth separately. The height of the dentine layer at point 2 was used as covariable. The results are given in detail in Tables I—II in the Appendix. Variations between sections (S) between measuring points (P) and their interaction (SP) were regarded as systematic variation between animals (=teeth T) was regarded as random variation as were the interactions tooth section (TS), tooth measuring point (TP), tooth section measuring point (TSP) and within replicates (R).

That the different variations can be neglected (null hypothesis no variation) can be investigated with F test. The analysis was performed by forming the following quotients for T, T TS, for S, S TS, for

P P IP for TS TS TSP for IP TP TSP for SP SP TSP and for TSP TSP R In the analyses of sets 3 4 and 5 the factor section (S) was replaced by factor interval (I) When forming the quotients T TS T TI TS and TI were chosen instead of TP because they were higher than TP Thus a model with variance components was used

For sets 3—4 and 4—5 the results are given in Table 2 All the systematic variations S P SP were considerable A high value for SP meant that the measuring points behaved differently in the different sections Of the variance components I and TI could be ignored because they did not differ significantly from 0 The others differed significantly from 0 and of them TS is to be noted This value meant that although the teeth were similar there was variation between sections This may be explained by the previously mentioned observation that all the sections of a given tooth may be placed too near the apex or the incisal edge The same explanation may apply to TSP If the values found for a given tooth are high in section 2 those for section 3 will be low and vice versa

In sets 3 4 and 5 the systematic variations I P and IP were large (Table 3) T could be ignored but the others differed significantly from 0 That TI TP and TIP could not be ignored may be due to differences between the positions of the sections in different teeth

To increase the number of animals available for analysis set 4—5 was analysed in right and left teeth taken together Each animal was represented by only one tooth The findings (Tables 1 and 2) were the same as earlier

Having shown the existence of a significant variation the next step was to describe the variation more closely

In the 5 sets and the 10 measuring points taken together polynomial regression was performed right and left side separately The purpose

Table 1 Mean weights and weight ranges in grams at beginning and end of experiment in different categories of adult female rats

was to describe the variation between sections or intervals with the aid of a polynomial of the lowest possible degree. A second degree polynomial was found suitable. With the thickness of the dentine layer is the dependent variable (Y) and interval or section is the independent variable (X). Y was calculated according to the formula:

$Y = \text{intercept} + (1\text{st}) \text{ regression coefficient } X + (2\text{nd}) \text{ regression coefficient } X^2$

The values for Y for 10 measuring points taken together and the number of animals used for calculations in each set are given in Table III and the standard deviations in Table IV. The corresponding graphs are found in Figs 10—14.

Fig. 19

Distances used for the analysis were DE pulp or DE band 5. These were chosen because they seemed to show the greatest variation. A mean value was calculated from the 2 replicates. Differences were found between animals and between right and left tooth from the same animal too. The variation between the right and left teeth was not smaller than that between animals. However no systematic difference was found between the right and the left teeth. The analysis was also performed for other categories of normal and hormone treated animals with the same results. It was therefore considered justified to use the data obtained from both the right and left side in the same animal in the analysis.

Fig. 17

Fig. 18

Polynomial regression was then performed for each of the 10 measuring points in the 5 sets. Because the right and left teeth were found to be similar the calculations were arbitrarily performed for the right side only. The calculated values for apposition of dentine and the number of animals on which they were based are given in Table V, the standard deviations in Table VI, and the graphical illustrations in Figs. 15—19.

Extended and simplified analysis. The curves hitherto obtained for the apposition of dentine supported the natural assumption that apposition in the different sets reflected only part of the apposition in the whole tooth. It was thought desirable to try to make full use of all the values measured in order to describe the pattern of apposition of dentine as completely as possible. Moreover the way in which the analysis had hitherto been performed was very time consuming, and a simplified method would be of value.

The measured values and the polynomials showed the right and the left teeth to be similar. To confirm this, analysis of variance was made

Fig. 19

Distances used for the analysis were DE pulp or DE band 5. These were chosen because they seemed to show the greatest variation. A mean value was calculated from the 2 replicates. Differences were found between animals and between right and left tooth from the same animal too. The variation between the right and left teeth was not smaller than that between animals. However, no systematic difference was found between the right and the left teeth. The analysis was also performed for other categories of normal and hormone treated animals with the same results. It was therefore considered justified to use the data obtained from both the right and left side in the same animal in the analysis.

As it had become clear that the positions of the sections varied somewhat from tooth to tooth another basis for classification was sought. Since the thickness of dentine increases towards the incisal edge it is obvious that the distance from the dento enamel junction to a fluorescent band increases towards the incisal edge. If for example interval 4 is chosen the values measured for this interval can be arranged according to the distance DE band 4. The higher the latter value the closer the section will be to the incisal edge. For a given value for DE band 4 the apposition of dentine for the following 4 days was known. The DE band values were divided into classes. DE band=1 (measuring unit) was the first class. DE band=2 was the second class etc. These classes were taken into groups of 5. 1—5, 6—10 and so on.

Data on all the 25 animals were used in this analysis. The calculations were made without the aid of a computer and could not easily be performed for every one of the 10 measuring points. It was thought suitable not to make them for the 10 points together. As the variation at point 2 was low this point was selected. This analysis was performed for time periods 8 and 4 days long, i.e., interval 3 and intervals 2, 4 and 5 pulp respectively. The animals were not of the same age during the different intervals. The intervals were compared in pairs. The differences between corresponding groups of classes were given different weights depending upon the number of observations added and compared to the standard deviation. A comparison between intervals 2 and 4 revealed no significant difference in apposition rate between them but between intervals 1 and 3 a highly significant difference existed. Intervals 2 and 4 were treated together and interval 3 was selected as representative of an 8 day interval. For the 4 day intervals it was decided to include the observations in interval band 5 pulp for DE band values higher than 50. Otherwise the values corresponding to high DE band values would have been rather few. The use of values measured between a fluorescent band and the pulp chamber may introduce an error as the inner border of dentine is difficult to identify. A comparison between the observations for interval 4 and band 5 pulp chamber revealed a wider variation among the latter but no significant difference. It was thought that the disadvantage of a somewhat wider variation was outweighed by the larger number of values on which to base the curve.

Tables VII—VIII give the number of values in each group of classes, the mean values and the standard deviation for individual values. The resulting graphs are in Figs. 20—21. On the X axis the thickness of the

dentine layer from the dento enamel junction to the actual band is given as values for the midpoints of the groups of classes. The corresponding measured values for apposition of dentine during the following 8 or 4 days are given along the Y axis. The curve for the 8 day interval is based on 183 observations and that for the 4 day interval on 499 measured values.

During the calculations it was also found that the standard deviations were larger when the values for DE band were high. The standard deviations are not given for each group of classes but a border was chosen between the 2 groups with midpoints 48 and 53 (Tables VII—VIII) because the increase of the standard deviations began there.

Age 10 months, low weight

This category comprised 9 animals. Mean weights and weight ranges are given in Table 1. All the animals are included in the analysis.

Analysis of covariance was performed and the details are given in Tables IX—X. The same model with variance components was applied

and the results are in conformity with those obtained for the 5 month old animals (Tables 4—5)

Polynomial regression was performed for the 10 points taken together and the results are given in Tables VI—VII and Figs 22—26. The general picture of apposition of dentine was the same as that obtained earlier. At this stage of the investigation it was not considered necessary to perform extended and simplified analysis for this category.

Fig 26

Age 11 months

This category comprised 16 animals. Mean weights and weight ranges are given in Table 1. Data on 13 were used in the computer analysis.

The details of analysis of covariance are given in Tables VIII—XV and in summary in Tables 6—7.

Polynomial regression was performed for the 10 measuring points taken together. The values for dentine apposition calculated from the polynomial are given in Table XV and the standard deviations in Table XVI. The corresponding graphs are Figs 27—31. The pattern of dentine apposition was essentially the same as in the categories investigated earlier.

Young animals

This category comprised 27 animals and the mean weights and weight ranges for males and females together during the experiment and for females only on day 28 are given in Table 8. On day 28 the mean weight for males was 237.9 grams and the range 208—278. The analysis

The results of covariance analysis are given in Tables VII—VIII. The same model with variance components as for the adult animals was applied and the result is given in Tables 9—10. The findings are the same as for the adult animals. The factors section interval and measuring point and their interactions are the important ones and their influences are highly significant. That factor tooth in one case is significant does not invalidate this statement. Concerning the significant interactions the same explanations may apply as to the adult animals.

The analysis was carried further and for the 10 points taken together the values measured were fitted to a second degree polynomial. The values calculated from the polynomial are given in Table IX and the standard deviations in Table X. The graphs are in Figs. 32—33.

The analysis of individual measuring points was performed only for set 4—5 right side. The calculated values and the standard deviations are given in Tables XI—XIII and the graph in Fig. 36.

In the extended and simplified analysis it was found necessary to treat the intervals of equal length separately because it was found that apposition of dentine during intervals 1 and 2 differed systematically and significantly from respectively 3 and 4. The mean values for

the different groups of classes the number of observations and the standard deviations for an 8 day and a 4 day interval are given in Tables XXIII and XXIV respectively. The corresponding graphs are Figs. 37—38.

The pattern for dentine apposition in young animals is essentially the same as in adult animals. The important exception seems to be that in young animals the course of events is faster. This can be seen for example in Fig. 34 which should be compared with Fig. 14 which illustrates the apposition of dentine in an adult animal. In section 5 both describe the events during the 24 day experimental period. In adults only the decrease in apposition can be seen while in young

animals the increase the maximum and the decrease occur during the same period

Determination of the age of the incisor at different levels

It has been shown that the sites of the sections varied somewhat from tooth to tooth and that the effect of this variation was overcome by the use of a different classification. It would be of even more value if an age determination could be made.

The following calculations were made with the aid of the earlier calculated means of values measured for apposition at point 2 for the 4 day intervals in the adult 2 month old animals (Table VIII). These values had earlier been arranged in groups of classes according to the distance from the dento enamel junction to the peripheral band of these intervals. The mean values for the groups of classes were known. If the mean value for a group of classes is added to the value for the midpoint of the group the sum denotes the apposition during an unknown time plus 4 days. To simplify the analysis distance in measuring units with even figures was chosen. With the rule of three the corresponding time in days can be calculated. The problem was however that the start of apposition of dentine had to be determined by extrapolation.

The reasoning is easier to follow if reference be made to Table 11. The midpoint of the first group of classes was 3 and the mean value for apposition during the following 4 days was 6.57. Then the mean thickness of the dentine layer at the end of these 4 days was 9.57. We selected distance 3—9. When the thickness of dentine increased from 3 to 9 six measuring units were added. Since we knew that the apposition of 6.57 units took 4 days it was calculated that apposition of 6 measuring units took 3.63 days. For the distance 0—3 it was assumed that the apposition of 6 measuring units took 4 days. Then 3 units took 2 days. These 2 days are added to the 3.63 days. Now we knew that the apposition of 9 units starting from 0 took 5.63 days. This procedure was used for the following groups of classes and the result is given in Table 11. The standard deviations of these age determinations were calculated (Table 11).

From the above-mentioned it follows that the X axis in Figs. 20—21 (points 34 and 37—38 (page 6)) may also denote time because the height of the dentine layer is related to time.

However it should be remembered that these age determinations

				97	50.8	0.5

are derived from observations of apposition at point 2 and are only valid for this point. Another limitation is that the beginning of apposition of dentine was determined by extrapolation.

SOURCES OF ERROR

The choice of systematic and random variations in the model for analysis of covariance may be regarded as well founded. The variations between sections, intervals, measuring points and their interactions are primarily the topic of the investigation. The F test showed that in a selected group of animals the variations between animals (T) were negligible compared with other variations studied. This is in accordance with general biological principles in experimental investigations.

Concerning the choice of a suitable degree for the polynomial it was thought that the second degree would fit most cases. To check this the F test was carried out and for different categories of normal animals it was found that a second degree polynomial was satisfactory.

This can also be shown by comparing the values measured for dentine apposition with those calculated with the aid of the polynomial. Table XXX gives the means of measured values at each of the points in the different sets for the 5 month old normal adult animals right side. On comparison of these values with the corresponding calculated values in Table V good agreement will be found. A curve of the third and fourth degree can always be adapted to 4 and 5 measured values respectively. From a biological point of view a function of the second degree seems to be natural and logical. It was then decided to describe the apposition of dentine as a second degree polynomial.

As it had been proved that highly significant differences existed between measuring points it was natural that the variations of the adapted curves were less for the individual points than for the points taken together. Tables IV and VI. Among the individual points 2 was the one with the least variation i.e. standard deviations for this point generally had the lowest values. This was shown for the different sets in the category of adult 5 month old animals. For the young ones it was calculated only for set 4—5 right side. Experience showed that measuring at point 2 was comparatively easy regardless of the age of the animals. It was therefore not considered necessary to make a complete computer analysis for all sets in young animals. Nor was it considered necessary to make this analysis for the older adult animals at this stage of the investigation.

The limitations of the age determinations of the incisor were mentioned in the description of the method. The standard deviations given describe the uncertainty of the mean values for apposition. The variation depending upon the systematic errors such as assumption of linear apposition of dentine and the selection of groups for the age determination are not included. This latter variation is hard to estimate but is probably not greater than the variation given.

DISCUSSION

Three phases could be recognised in the curve for the rate of apposition of dentine: a rising one, a maximum one and a falling one. The result was the same whether it was based on measurements made during a given time interval in different sections or during different time intervals in sections. The general pattern was the same whether the curves were based on the values noted at a single measuring point or the 10 measuring points were combined to a "mean" measuring

point. In the former case there were obvious differences between the different points with regard to the magnitude of the measured values and also with regard to the occurrence of the maximum of apposition (Figs 15—19 36, pages 49—51 and 62). When all the measured values from point 2 were exploited for the investigation of the appositional rate as described in the simplified analysis again the same pattern emerged.

Thus when 3 different methods were used for the analysis the same picture of dentine apposition was obtained in 4 experimental categories of animals.

Though it appeared improbable that a fundamental methodological error was the cause of the variation found the method for taking histologic sections may have been touched upon. Sections with number 3 were those closest to the radius of the tooth and the values for dentine apposition in these sections ought to be closest to the true values. Sections from the apical and incisal parts deviated from the radius and the values found for apposition of dentine were 'too large'. The values measured and accounted for previously however showed the opposite pattern. The conclusion can be drawn that the deviation of the sections from the radius counteracts rather than contributes to the variation found in apposition of dentine. In the statistical investigation of the variation between intervals in one and the same histologic section deviation of the section from the radius has no effect on the proportions between the intervals. That observations at point 2 were selected for the simplified analysis may to some extent have reduced the error connected with the cutting of segments. In one plane a possible rotation of the section may occur round an axis roughly corresponding to the place where measurements at point 2 are performed and if this occurs the measured values are affected little or not at all by this error.

The conclusion may be drawn that there are good reasons to assume that the variation in the rate of apposition of dentine found and described is true and not simply apparent. Even visual inspection of the histologic sections shows a variation (Figs 39—43).

Schour and co workers (page 17) who investigated this subject did not describe this variation in apposition of dentine and this may at least partly be attributed to their technique. A survey of their reports shows that they used both transverse and sagittal sections from the incisors for measurements but — as far as can be seen — they used only 1 transverse section per tooth. The technical difficulties in making longitudinal sections may explain why the variation was not discovered in these. It is also impossible to know with certainty from

Fig. 39

Figs 39—43 Microphotographs of sections 1—5 from an 11 month old normal animal 1: 39 section 1 4 fluorescent bands (2—3) visible Fig 40 section 2 4 fluorescent bands (2—3) clearly visible band No 1 is discernible under the enamel (top of the picture) Figs 41—43 sections 3 4 and respectively Five fluorescent bands visible 37×

their reports where on the circumference of the tooth the measurements were made Weinmann (1942) mentioned differences similar to those reported above but he thought them to be due to the toxicity of his marking substances

A search of the literature revealed no reports indicating that the variation of dentine apposition in the white rat's upper incisors has ever been so closely described as in the present investigation

When the pattern of apposition of dentine was compared in the 3 categories of animals of different ages and normal weights it was found that young animals differed considerably from adult animals The course of events was much faster in young animals (Figs 19 and 34 pages 51 and 61) In young animals apposition during intervals 1 and 2 differed highly significantly from that during intervals 3 and 4 respectively The difference may perhaps be explained by the quicker development of the animals at this age Consequently the different ages

Fig. 40

Fig. 41

Fig. 42

Fig. 43

Fig 40

Fig 41

Fig. 42

Fig. 43

Fig 44 Dentine apposition in normal animals of different ages λ axis mean value from 4 day intervals 2 and 4 λ axis midpoints of groups of classes (=age of the formative cells) $\circ - \circ - \circ$ 5 month old animals $\circ \quad \circ \quad \circ$ 11 month old animals $\circ \quad \circ \quad \circ$ young animals

of the animals during different intervals affects dentine apposition more in young animals than in adults

In the 2 categories of adult animals of normal weight age about 5 and 11 months respectively the differences in pattern of apposition were much smaller despite a comparatively larger difference in age (Fig. 44). The 10 month old animals of low weight differed somewhat from those with normal weight. During the increase in rate of apposition of dentine the difference was small but the maximum occurred somewhat earlier and was not of the same magnitude as in the animals with normal weight and the decrease was somewhat more rapid.

The age determinations were founded on observations made at point 2 and are valid only for this point. They are based upon the formation of dentine. They cannot forthwith be used to describe the chronological age of the odontoblasts corresponding to point 2 but denote the "functional age" of these odontoblasts. It is true that the difference may be small but the distinction ought to be made. With the method described age determinations can be made for any point if the laws of growth

Fig. 45. Height of the dentine layer (Y axis) versus incisor age in days (X axis) of a month old normal animal (cf Table II).

of the incisor are to be analysed further. For this investigation no such further analysis was necessary.

If desired the appositional rate in μm per day can be calculated by multiplication of the figures given by 10 and division by the actual interval in days (4, 6 or 8). If it is made for sections 3 point 2 in a month old animals with the aid of values calculated from the polynomial (Table V) it will be found that the mean rate increases from 18.5 μm during interval 1 to 23.0 μm during interval 4. Much greater differences can be found for other measuring points and other sections.

If the curve for height of the dentine layer versus time (Fig. 45) is studied a slight but discernible S form can be found. This S form though more marked is found in curves describing other types of growth such as weight in relation to age of the rat (Zucker, Hall, Young & Zucker 1941; Zucker & Zucker 1942), the number of individuals in relation to age in a population and weight in relation to age of individuals (Brody 1945). Thus the growth of incisor dentine is in agreement with some other types of growth.

The comparison between the formation of 2 types of calcified tissues, dentine in the rat incisor and bone in an osteone may be of interest. Jee & Arnold (1954) using Ca^{45} as a tracer found that the rate

of bone apposition in a Haversian system was highest during the first half of the formation process Marshall Jowsey & Rowland (1969) made similar findings Lee (1964) studied the bone formation rate in osteones with the aid of tetracycline markings and found a linear relationship between appositional growth rate and diameter of the marker. However he admitted that at the lower rates of growth the correlation was not so good. Frost (1964) described the rate of bone formation in a Haversian system by means of an S shaped curve based on a histogram.

It is possible that different forms of growth can be described by S shaped curves. As measurement at low rates of growth may be difficult the values forming the basis of the 2 ends of the curve may be difficult to obtain. If a method does not allow measurement of low rates of growth it will record only the fairly linear part of the curve. This may explain the discrepancies between the findings by different authors regarding Haversian systems.

APPPOSITION OF DENTINE UNDER INFLUENCE OF PITUITARY GROWTH HORMONE AND OF HYDROCORTISONE

INTRODUCTION

The purpose of this study was to find out whether administration of either of the hormones had any effect on the rate of growth of dentine. The growth hormone was studied for its effect on both adult and young animals, hydrocortisone only on adult animals.

CHOICE OF HORMONE PREPARATIONS

Growth hormone can be obtained from different sources. The porcine growth hormone preparation Somacton has previously been used in investigations in man and experimental animals.

Carstensen, Paulsen & Rudberg, Roos (1955) gave Somacton and insulin to patients with advanced pulmonary tuberculosis and in 8 cases they found "definite improvement of the general condition in all but one patient and a weight increase in all but two cases". Srikku (1956) found Somacton to have a maturing effect on granulation tissue and to increase the tensile strength of healing experimental wounds. Brummer (1966) studied the formation of adhesions around a traumatised tendon and found Somacton to accelerate the formation of collagen.

Somacton has been reported to accelerate healing of fractures of the tibia in the rat (Koskinen 1959). Even in combination with thyrotropin it is said to promote fracture healing in humans (Koskinen 1963).

It was decided to use this preparation of growth hormone¹ because it was fairly readily available and second because it has been reported to have positive effect also on the formation of mineralised tissue.

of bone apposition in a Haversian system was highest during the first half of the formation process Marshall Jowsey & Rowland (1959) made similar findings Lee (1964) studied the bone formation rate in osteones with the aid of tetracycline markings and found a linear relationship between appositional growth rate and diameter of the marker. However he admitted that at the lower rates of growth the correlation was not so good Frost (1964) described the rate of bone formation in a Haversian system by means of an S shaped curve based on a histogram.

It is possible that different forms of growth can be described by S shaped curves. As measurement at low rates of growth may be difficult the values forming the basis of the 2 ends of the curve may be difficult to obtain. If a method does not allow measurement of low rates of growth it will record only the fairly linear part of the curve. This may explain the discrepancies between the findings by different authors regarding Haversian systems.

10 or 10 I U GH it was decided to give 10 I U of GH daily to adult animals and 2 I U daily to young animals which doses are well above those used by Koskinen (1959)

The supply of hydrocortisone could be regarded as unlimited. In young rats Johannessen (1964) found oral administration of cortisone to retard dentinogenesis in the molars. The dose is not expressed in mg per kg bodyweight but judging from the figures given it varied between 17 and 40 mg/kg bodyweight. Ellis Jr (1951) found 20 mg cortisone acetate per kg bodyweight to have no effect on the epiphyseal cartilage in the rat. Profound disturbances occurred when the dose was 40 or 50 mg. Stanisavljevic et al (1962) found a daily dose of 1 mg hydrocortisone acetate to retard lamellar bone formation. In the present investigation it was decided to give a daily dose of 20 mg (vol 1 ml) hydrocortisone i.e. a very large dose.

The doses of GH and hydrocortisone were not intended to be comparable.

ROUTE OF ADMINISTRATION

According to Greenspan et al (1949) the effect of GH investigated by the tibia test is the same whether the hormone is given subcutaneously, intraperitoneally or intravenously. It was decided to give GH subcutaneously to the adult animals and to reserve the intraperitoneal route for the suspension of hydrocortisone acetate in case it should be desired later to give the two hormones simultaneously. Because of the smallness of the young animals it was easier to inject GH intraperitoneally. Hydrocortisone has been reported to be effective when given intraperitoneally (Stanisavljevic et al 1962).

MATERIAL AND METHODS

Adult animals

Two series of experiments, primary experiments and control experiments were performed.

Primary experiments

Thirty two female rats were divided into 2 equal groups. One group was given a daily intraperitoneal injection of 20 mg (1 ml) hydrocortisone acetate and the other a daily subcutaneous injection of 10 I U porcine GH (1 ml) on the last 12 days of the earlier used experimental period corresponding to intervals 3 and 4. At end of the experiment the

The hormone was delivered in vials containing 50 IU of GH (in dry substance). Before use it was dissolved in 5 ml of solvent. The solvent consisted of distilled water containing 5 per cent glucose and 0.5 per cent phenol. With the aid of hydrochloric acid the pH was adjusted to 3—4.

Stamisljevic et al (1962) reported that hydrocortisone acetate retarded lamellar bone formation more than cortisone acetate. In their study of callus formation Hulth & Olerud (1964) used cortisone acetate (Cortodrin® Astra) which was found to retard bone repair. The same manufacturer's preparation of hydrocortisone acetate (Hydrocortodrin® Astra)² was used in the present investigation.

It is a suspension containing 25 mg of hydrocortisone acetate (17 hydroxycorticosterone 21 acetate) per millilitre. The suspension medium used in the control experiments was supplied by the manufacturer. It contains Tween 80, phenylcarbinol, carboxymethylcellulose, sodium chloride and distilled water.

The descriptions of the hormones, the solvent and the suspension medium have been obtained from the manufacturers.

DURATION OF HORMONE TREATMENT

It was intended to study dentine formation before and during hormone treatment in one and the same animal. The duration of hormone treatment was selected so that the earlier used investigation period (24 days) was divided into 2 parts. In the beginning and without knowledge of the effect of the above hormones on dentine formation it seemed natural to use a control period of the same length as the period of treatment. It was considered self evident that the control period should precede the hormone period.

DOSAGE

It was decided to use such large doses that a lack of response could not reasonably be ascribed to too small a dose.

When deciding upon the dose of GH it had to be taken into account that the supply was not unlimited and that the protein solution might cause local irritation. If such a reaction occurred it might interfere with the result. When choosing between 1/2 and 1 millilitre of solution

² Generously supplied by AB Astra, Södertälje.

RESULTS

*Effect of growth hormone**Adult animals*

Primary experiments The weights of the animals during the experiment are given in Table 12. On day No. 28 the mean weights of the animals in the different sets ranged from 283.0 to 293.7 grams.

The computer analysis is based on values from 12 animals and the simplified analysis on values from 16.

The results of analysis of covariance are given in Tables XXXI—XXXII and summarised (page 46) in Tables 13—14. It is seen that the factors S, I and P and their interactions are the chief sources of variation. To the exceptions the same explanations may apply as by the normal animals.

The statistical analysis was carried further to include polynomial regression. This was based on the means of the values recorded for the 10 measuring points in each of the sets, right and left side separately and for each of the points in the sets on the right side. Analysis with the aid of F test revealed that apposition could be satisfactorily described with a second degree polynomial. The calculated values for apposition of dentine, the number of animals and the standard deviations are given in Tables XXXIII—XXXIV. If these values are compared with the corresponding values in normal 5 month old animals (Tables III and V) a general pattern will emerge. The rate of dentine apposition in the GH treated animals was as a rule lower than in the untreated animals during the period before hormone treatment but during this treatment it rose and was finally higher. This finding was the same whether the values were analysed for each measuring point separately or whether the values formed at all 10 points were pooled before analysis. This means that this investigation failed to show that dentine formation corresponding to any particular measuring point is

Range	176—380	210—290	263—316	244—310

animals were a little more than 4 months old. The different techniques used were the same as those described in Chapter IV.

Control experiments

One hundred female rats were divided into 5 equal groups of practically the same mean bodyweight. The cages were randomly distributed in the stable. Five injections of OTC were given at 6 day intervals; otherwise the animals were treated in the way described earlier. Intervals of equal length were used to facilitate the simplified analysis. At the end of experiment the animals were slightly above 4 months.

Of those 100 animals, group 1 served as untreated controls, while the other 4 groups received various injections:

- 1) No treatment
- 2) Daily subcutaneous injection of 10 IU (1 ml) of porcine GH during the last 12 days of the experimental period
- 3) Daily subcutaneous injection of 1 ml solvent for GH during the last 12 days of the experimental period
- 4) Daily intraperitoneal injection of 25 mg (1 ml) hydrocortisone acetate during the last 12 days of the experimental period
- 5) Daily intraperitoneal injection of 1 ml of the suspension medium for hydrocortisone acetate during the last 12 days of the experimental period

The previously described histologic and measuring techniques were used with the exception that measurements were made only at measuring point 2 and always by the author personally. When making the measurements the author did not know to which group of animals a given histologic section belonged. Some of the observations were checked by the technical assistant in randomly selected sections.

Young animals

Forty-five animals received daily intraperitoneal injection of 2 IU GH and 17 the corresponding volume (0.2 ml) of solvent for GH during the last 12 days of the experimental period. At the beginning of experiment 30 days.

RESULTS

*Effect of growth hormone**Adult animals*

Primary experiments The weights of the animals during the experiment are given in Table 12. On day No. 28 the mean weights of the animals in the different sets ranged from 283.0 to 293.7 grams.

The computer analysis is based on values from 12 animals and the simplified analysis on values from 16.

The results of analysis of covariance are given in Tables XVI—XXII and summarised (page 46) in Tables 13—14. It is seen that the factors S, I and P and their interactions are the chief sources of variation. To the exceptions the same explanations may apply as by the normal animals.

The statistical analysis was carried further to include polynomial regression. This was based on the means of the values recorded for the 10 measuring points in each of the sets, right and left side separately, and for each of the points in the sets on the right side. Analysis with the aid of F test revealed that apposition could be satisfactorily described with a second degree polynomial. The calculated values for apposition of dentine, the number of animals and the standard deviations are given in Tables XXIII—XXVI. If these values are compared with the corresponding values in normal 5 month old animals (Tables III and V) a general pattern will emerge. The rate of dentine apposition in the CH treated animals was as a rule lower than in the untreated animals during the period before hormone treatment but during this treatment it rose and was finally higher. This finding was the same whether the values were analysed for each measuring point separately or whether the values formed at all 10 points were pooled before analysis. This means that this investigation failed to show that dentine formation corresponding to any particular measuring point is

Fig. 46 Calculated variation of dentine apposition Set 4 10 measuring points taken together — 4 month old normal animals — — 4 month old animals treated with growth hormone during latter half of experimental period — — 4 month old animals treated with cortisol during latter half of experimental period Primary experiments

more susceptible than others to GH. To save space it was not considered necessary to illustrate the findings graphically so completely as in the normal animals. A representative curve for normal apposition and for comparison the corresponding curve for animals under the influence of GH are given in Fig. 46 from which it is clear that the 2 curves are very similar in shape they are only somewhat apart. This interspace may reflect a true difference between the 2 categories of animals but it may also depend upon an altered rate of eruption or a systematic error in the positions of the sections.

The findings were analysed by the simplified method. Apposition during both an 8 day (3) and a 4 day (4) interval in 6 month old untreated animals was compared with that during the corresponding intervals in animals treated with GH. No significant differences were found.

When the two 8 day intervals were compared with each other in the same category of animals it was found that in the untreated animals there was a highly significant decrease of the rate of dentine apposition during interval 3 compared with that during interval 1 but no such difference was found in the GH treated animals.

When the two 4 day (2 and 4) intervals were compared with each other in the normal category and in the category of GH treated animals it was found that in the normal animals the rate of apposition of dentine tended to be somewhat lower during interval 4 than during interval 2 but the difference was not significant. In the GH treated animals the rate of dentine apposition was higher during interval 4 when the animals were given GH than during interval 2 when no treatment was given. The difference was almost significant.

Control experiments. The mean weights and weight ranges are given in Table 15. The data were analysed by the simplified method and the numbers and means of the measuring values for untreated, GH treated and solvent treated animals are given in Tables XXXII—XXXIV. This analysis is based on values from all the animals. In the analysis only the mean values for the groups of classes with midpoints from 3 to 38 inclusive were used because these groups showed the least variation around mean values. The standard deviations in the different categories were close to each other and for the calculations one and the same estimate 0.8 was used. The standard deviation of mean values was calculated by dividing 0.8 by the square root of the number of observations (n).

Comparison of pairs of categories of animals (no treatment versus treatment with CH, treatment with GH versus treatment with solvent

differences were found. The difference between intervals 1 and 2 cannot be satisfactorily explained. It may be due to chance.

In animals treated with GH no difference was found between intervals 1 and 2. The rate of apposition of dentine was highly significantly greater during interval 3 than during 2 and highly significantly lower during interval 4 than during interval 3.

In animals given solvent for GH no significant differences were found between the intervals.

The results are illustrated in Fig. 47.

Young animals

The mean weights and rings are given in Table 8 (page 59).

Since extensive analysis of covariance had been performed for normal adult animals, normal young animals and hormone treated adult animals and shown the same general pattern it was not considered necessary to perform this analysis for every set of the GH treated young animals. It was thought sufficient to perform it for sets 4—5 and 6, right side, i.e. one interval in different sections and different intervals in one section respectively. The choice of the right side was arbitrary and consistent with the earlier choice of the right side for certain statistical calculations. The detailed results are given in Table XXX and in summary in Table 16. The findings agree well with those made earlier.

Polynomial regression was performed for the above mentioned sets. Also in this category of animals apposition of dentine could be satisfactorily (F test) described with a second degree polynomial. The results for all 10 measuring points taken together are given in Table

XXXXVI and for each of the points in set 4—5 right side in Table XXXVII. The corresponding standard deviations are given in Tables XXXVIII and XXXIX respectively. The general pattern is the same as earlier.

The data from normal GH treated and solvent treated animals were analysed by the simplified method. Comparisons were made only between intervals of equal length, i.e. 1 versus 3 and 2 versus 4. The material is presented in Tables XL—XLII. The groups of classes with midpoints above 38 were not included because of the increase in variation in the higher groups of classes. The standard deviations were estimated at 0.7 for intervals 2 and 4 and at 1.1 for intervals 1 and 3. The standard deviations for the mean values were obtained by dividing these figures by the square root of the number of measuring values (n).

When the 3 categories normal (page 56) GH treated and solvent treated were compared with regard to intervals 1 and 2 (no treatment) it was found that no differences existed between the 3 categories. For this comparison each of the intervals 1 and 2 were compared in the following way: normal versus solvent treated, normal versus GH treated and solvent treated versus GH treated. During intervals 3 and 4 (treatment intervals) the rate of apposition of dentine was highly significantly greater in GH treated animals than in those given solvent but — surprisingly — those animals given solvent had a highly significantly greater rate of apposition than those not treated. The results are illustrated in Fig. 48.

When no treatment and treatment periods were compared with each other in the same category of animals the following results were obtained:

In normal animals there was (as mentioned earlier) a highly significant decrease in the rate of apposition of dentine during intervals 3 and 4 compared with the rate during intervals 1 and 2 respectively.

In animals treated with GH there was no decrease during interval 3 (treatment with hormone) compared with interval 1 (no treatment). The number of observations was however comparatively small. The decrease during interval 4 (treatment with GH) compared with interval 2 (no treatment) was also smaller than in the normal animals and was not significant.

In animals given solvent for GH there was a highly significant decrease during intervals 3 and 4 compared with intervals 1 and 2 respectively. Thus the findings were the same as in the normal animals.

The effect of the administration of the preparation of porcine growth

Fig. 48 Observed variation of dentine apposition in young animals. Those for intervals 2 and 4 have been doubled. \circ \circ normal animals \circ — \circ animals treated with growth hormone during latter half of experimental period \circ \circ animals treated with solvent for growth hormone during latter half of experimental period. The curves are comparable only at the vertical axis (cf. Table XIII).

hormone used here may be summarised as follows. In adult animals the rate of apposition was highly significantly increased only when the treatment free period was compared with the period of treatment in the same category of animals. In young animals an increased rate of apposition was found during the period they were given solvent for growth hormone. During the period when growth hormone was given a highly significant increase was detected both within the category of hormone treated animals and when this category was compared with the category treated with the solvent.

Effect of hydrocortisone

Adult animals

Primary experiments The weights of the animals are given in Table 17.

During the measurements it was found that the outline of the pulp chamber was abnormally wavy and irregular (Fig. 49) and it was difficult or impossible to measure the distances between fluorescent bands. Already at this stage of the investigation the rate of apposition of dentine appeared reduced.

The material available for statistical analysis was less complete than in the other categories. The computer analysis was based on values from 8 animals and the simplified analysis on values from 10.

Table 17 Mean weights and weight ranges in grams during experiment 4 month old animals Treatment with cortisol during latter half of experimental period Primary experiments

Day	0	12	24	38
Mean weight	258.1	256.4	203.5	191.8
Range	240—276	237—273	182—222	180—218

The results of the analysis of covariance (Table XI III) are summarised in Table 18. In set 4 right side there was one exception to the earlier rules: the factor interval was not found to be significant and the factor point (P) was only almost significant. Otherwise the results were essentially the same as before.

Polynomial regression was performed for the 10 points taken together. It showed a second degree polynomial to be acceptable. The results are given in Tables XLIV—XLV. The rate of apposition of dentine was decreased (Fig. 46, page 78). When the individual measuring points were to be analysed it was found that the material being small

would not allow an analysis for each of the points. This analysis was therefore confined to measuring point 2. The results are given in Tables XVI—XLVII.

A simplified analysis based upon observations made in 15 animals was performed and when the two 4 day intervals 2 (no treatment) and 4 (treatment with cortisol) were compared it was found that the rate of apposition of dentine was highly significantly decreased during cortisol treatment.

Control experiments. One of the cortisol treated animals died from unknown cause on the third day of treatment. The weights are given in Table 15 (page 80).

Simplified analysis was performed and the number of observations and the mean values for animals treated with cortisol and for animals treated with suspension medium are given in Tables XVIII—II. The results are based on observations made in all surviving animals. In the analysis only the mean values from the group of classes with mid points from 3 including 39 were used because these groups showed the least variation. The estimated standard deviations were 0.8 and 0.9 respectively.

When the animals treated with the suspension medium for cortisol were compared with the untreated animals no difference was found between apposition during intervals 1 and 2. During intervals 3 and 4 the animals given suspension medium showed a significant decrease in rate of apposition.

When the 4 intervals in the category given suspension medium were compared with those in the category treated with CH solvent no significant difference was found for any interval.

would not allow an analysis for each of the points. This analysis was therefore confined to measuring point 2. The results are given in Tables XLVI—XLVII.

A simplified analysis based upon observations made in 15 animals was performed and when the two 4 day intervals 2 (no treatment) and 4 (treatment with cortisol) were compared it was found that the rate of apposition of dentine was highly significantly decreased during cortisol treatment.

Control experiments. One of the cortisol treated animals died from unknown cause on the third day of treatment. The weights are given in Table 15 (page 80).

Simplified analysis was performed and the number of observations and the mean values for animals treated with cortisol and for animals treated with suspension medium are given in Tables XVIII—II. The results are based on observations made in all surviving animals. In the analysis only the mean values from the group of classes with mid points from 3 including 38 were used because these groups showed the least variation. The estimated standard deviations were 0.8 and 0.8 respectively.

When the animals treated with the suspension medium for cortisol were compared with the untreated animals no difference was found between apposition during intervals 1 and 2. During intervals 3 and 4 the animals given suspension medium showed a significant decrease in rate of apposition.

When the 4 intervals in the category given suspension medium were compared with those in the category treated with CH solvent no significant difference was found for any interval.

When the cortisol treated animals were compared with those given suspension medium regarding the periods before treatment it was found that apposition during interval 1 in the cortisol treated group was significantly lower than in the solvent treated group while intervals 2 showed no significant difference. No satisfactory explanation can be offered for this. Anyhow during the 6 day period immediately preceding treatment the 2 categories were without detectable difference. When intervals 3 and 4 in the 2 categories were compared it was found that the rate of apposition of dentine was highly significantly lower during hormone treatment than during administration of the suspension medium.

When the different intervals were compared with each other in the same category of animals i.e. 1 versus 2, 2 versus 3 and 3 versus 4 no differences were found in the category of animals given suspension medium for cortisol.

Animals treated with cortisol showed a highly significantly decreased rate of dentine formation during interval 3 compared with 2. The rate of dentine formation was also highly significantly lower during interval 4 than during 3 (Fig. 47, page 80).

Functional age of formative cells and response to hormone

When the analyses were made it was presumed that if the hormones had any effect it would be detectable even if groups of odontoblasts of different ages (=different midpoints of classes) were investigated together. The choice of the groups of classes to be included in the analysis was made mainly for statistical reasons. A possible refinement would be to investigate the response in each group of classes compared with that in corresponding untreated groups. If such a comparison is to be made it should be noted that the only place where treatment is strictly comparable to no treatment is at the transition between the 2 periods in the present investigation between intervals 2 and 3. If the effect of treatment is small compared with the width of the groups of classes selected it can also be made at the transition between intervals 3 and 4 without introducing any error of importance. But if the effect of treatment is substantial it will not correspond to the thickness of the dentine layer in the same way as earlier and then the comparison cannot be made or it will have to be corrected for the influence of treatment before the place of comparison.

That the influence of treatment can vary with the age of the cells

APPOSITION

FIG. 50 Observed apposition of dentine during interval 3 (16 days control experiment) in normal animals (O---O) and in animals given cortisol (O---+---O). Those odontoblasts with the highest appositional rate seem to be affected most.

is illustrated in Figs. 50—51. Fig. 50 corresponds to interval 3 and it is seen that those cells with the highest appositional rate seem to be the ones affected most by the administration of cortisol. Fig. 51 corresponds to interval 4 and the result is the same as earlier, only more accentuated and the older cells are also affected. The younger ones seem to be more resistant to cortisol.

Summarising, a retarding effect of the suspension medium was found but in animals given cortisol the rate of apposition of dentine is highly significantly lower during treatment than in normal animals and in those given the suspension medium for the hormone. This finding is the same whether the 2 experimental categories are compared with each other or treatment and no treatment periods in the cortisol treated category.

When the cortisol treated animals were compared with those given suspension medium regarding the periods before treatment it was found that apposition during interval 1 in the cortisol treated group was significantly lower than in the solvent treated group while intervals 2 showed no significant difference. No satisfactory explanation can be offered for this. Anyhow during the 6 day period immediately preceding treatment the 2 categories were without detectable difference. When intervals 3 and 4 in the 2 categories were compared it was found that the rate of apposition of dentine was highly significantly lower during hormone treatment than during administration of the suspension medium.

When the different intervals were compared with each other in the same category of animals i.e. 1 versus 2, 2 versus 3 and 3 versus 4 no differences were found in the category of animals given suspension medium for cortisol.

Animals treated with cortisol showed a highly significantly decreased rate of dentine formation during interval 3 compared with 2. The rate of dentine formation was also highly significantly lower during interval 4 than during 3 (Fig. 47, page 80).

Functional age of formative cells and response to hormone

When the analyses were made it was presumed that if the hormones had any effect it would be detectable even if groups of odontoblasts of different ages (=different midpoints of classes) were investigated together. The choice of the groups of classes to be included in the analysis was made mainly for statistical reasons. A possible refinement would be to investigate the response in each group of classes compared with that in corresponding untreated groups. If such a comparison is to be made it should be noted that the only place where treatment is strictly comparable to no treatment is at the transition between the 2 periods in the present investigation between intervals 2 and 3. If the effect of treatment is small compared with the width of the groups of classes selected it can also be made at the transition between intervals 3 and 4 without introducing any error of importance. But if the effect of treatment is substantial age will not correspond to the thickness of the dentine layer in the same way as earlier and then the comparison cannot be made or it will have to be corrected for the influence of treatment before the place of comparison.

That the influence of treatment can vary with the age of the cells

skeletal tissues of intact white rats have been made after long periods of treatment with GH. Brumbe, Becks & Evans (1954) gave adult rats GH for 436 days and found an increase in tooth size. When Asling & Evans (1961) described the effects on skeletal development of GH in excess to normal growing female rats starting at 81 days of age* they considered administration of GH for 30 days a short term experiment. When studying the induction of gigantism in rats by GH, Asling, Simpson & Evans (1965) administered the hormone for 8 months or more. The period of hormone treatment used in the present investigation 12 days was therefore comparatively short. This must be borne in mind in the appraisal of the results.

In *adult animals* the primary experiments indicated that GH had an accelerating effect on dentine formation. In the control experiments the rate of dentine formation was greater during the period when GH was given than during the period without treatment when these 2 periods were compared with each other in the same category of animals. The difference was highly significant when intervals 2 and 3 were compared. However the increase did not continue during interval 4 but a drop occurred as compared to interval 3. Still the rate was somewhat higher than during the period with no treatment.

In *young animals* the pattern seems somewhat more distinct. When the apposition in 3 categories—normal, GH treated and solvent treated animals—were compared regarding the period preceding treatment they were found not to differ significantly from one another. When the second parts of the experimental period, i.e. the intervals when treatment was given, were compared it was found that the rate of apposition of dentine in the solvent treated animals was highly significantly greater than in normal animals and that the rate was highly significantly greater in the GH treated animals than in the solvent treated.

When the periods without and with treatment were compared in each category of animals it was found that both normal and solvent treated animals showed a highly significant decrease in the rate of apposition of dentine during the intervals corresponding to treatment. When the animals were given GH this decrease did not occur and no significant differences were found.

The highly significant difference found between normal and solvent treated animals was unexpected. Several tentative explanations may be offered but no definitive answer can be given. The route of administration may play a role in spite of earlier investigations denying this possibility (Greenspan et al 1949). It may be due to one or more

APPOSITION

Fig. 31. Interval 4 in the same categories of animals as in Fig. 30. Young cells seem to be affected least.

DISCUSSION

To begin with it should be stressed that the purpose of the experiments was not to make an extensive endocrinological investigation of the effects of GH and cortisol on the rate of incisor dentine formation but simply to find out whether the formation rate could be accelerated or retarded by the administration of hormones (GH and cortisol). As the pattern of apposition was known only for normal animals it was natural to give excessive doses of the hormone to intact animals. The effects of removal of the natural endocrine gland(s) and the effects of substitution therapy would have required investigations of dentine apposition in hypophysectomised or adrenalectomised animals.

Growth hormone

Earlier investigations of the effect of pituitary GH on dental and

vent for GH. The suspension medium is more complex than the solvent for GH and it is possible that it can disturb the formation of dentine. Earlier investigators (Branemark & Goldie 1967, Branemark, Goldie & Lindstrom 1967) have found deleterious effects of the suspension medium for a corticosteroid preparation when locally applied to experimental animals. The effect was found attributable to sorbitol.

At present the findings can only be noted; no definite explanation can be offered and further investigations are desirable. Anyhow, the difference between animals given suspension medium and those given cortisol was so great that no doubt should exist that cortisol itself in the dosage employed has a profoundly retarding effect on the rate of incisor dentine apposition.

The present investigation has not shown how the hormones exert their effects. A very complicated chain of events may be at work. The effects found are connected with the administration of the hormones. Similar effects were obtained by administration of the solvent respectively the suspension medium, but the effect of the hormones were highly significantly different from that of the suspension medium or the solvent alone.

constituents of the solvent. It is possible that the handling of the animals every day during the experimental period is the cause. It has been claimed that the more rats are handled the tamer and quieter they become and then probably grow more quickly (Irene Petter 1963). This assumption may be supported by the fact that the effect of solvent was only seen in young animals which can be expected to be more sensitive than adults. It has been claimed that children subjected to stress grow taller and it seems certain that stimulation of rats during infancy may cause increase in the rate of growth (Whiting Landauer & Jones 1968).

With the method developed measurements can be performed with high precision. This fact and the possibility that the test system is easily influenced by various factors especially in young animals may explain the unexpected finding.

It is not easy definitely to decide whether GH has an effect or not. Even if highly significant differences were found the absolute differences between the values measured were not so large (Tables VIII—XIV, VI—XLII). However and this may be the important finding in all of the 3 categories of animals treated with GH: adult animals both primary and control experiments and young animals the results of GH treatment point in the same direction and indicate that GH has an accelerating effect on upper incisor dentine formation in the intact female white rat. The conclusion may be drawn that it is highly probable that a true and not an apparent effect was found. The results are in conformity with those obtained by earlier investigators who used longer experimental periods and less precise methods.

Hydrocortisone

A retarding effect was demonstrable already in the histologic sections (Fig. 49, page 84). Also the values measured (Tables XVI—II) clearly demonstrated that a decrease occurred and the final proof was produced by the statistical analysis which showed a highly significant decrease during cortisol treatment. Young odontoblasts seem to be less responsive than older ones (Figs. 50—51, pages 87—88).

Again the vehicle was found to have an effect in the same direction as the hormone. In the interpretation of the fact that the decrease compared with that in normal animals was significant but not highly significant it should be borne in mind that no difference was found between the effect of suspension medium for cortisol and that of the sol-

RESULTS AND DISCUSSION

In the specimens from untreated animals neither on the endosteal nor on the periosteal side was bone formation present on the whole circumference of the bone at the same time. Parts of the circumference showed bone formation and at these places fluorescent bands were visible (Fig. 52).

A possible source of error should be mentioned. Though only 5 injections of OTC have been given 6 fluorescent bands were visible. This can be explained by the observation that during the grinding of sections OTC is dissolved from the bone and is present in the water during grinding and is absorbed to the surface of bone. The same finding can be made in dentine. If a section from a tooth from an animal given no injections of OTC is ground with the aid of equipment previously used for the grinding of sections from animals given OTC a fluorescent band will be found in the boundary between dentine and the pulp chamber. If a section from an animal given no injections of OTC is ground with

TENTATIVE COMPARISON BETWEEN APPPOSITION OF INCISOR DENTINE AND LAMELLAR BONE

INTRODUCTION

Garn, Lewis & Blizzard (1965) compared dental and skeletal development in some endocrine disturbances in man. They found that the retardation or acceleration of development was less pronounced in dental than in skeletal tissues, in dental tissues only half as much or one fourth of that in skeletal tissues. In congenital adrenal hyperplasia Bergstrand & Filipsson (1967) preliminarily reported a similar finding, dental development was less advanced than skeletal development.

In the present investigation an attempt was made to compare the formation of dentine and of lamellar bone.

MATERIAL AND METHODS

As mentioned above the femur and the tibia on each side had been extracted and stored in the cold. For the investigation the right femur and tibia were selected from the following experimental categories: 5 month old normal adult animals, 4 month old animals given GH or cortisol (primary experiments) and the 4 month old adult animals used for control experiments. Only those animals where the investigation of the dentine had shown no missing fluorescent bands were used.

From the middle third of the unembedded femur and the tibia 3 transverse sections were taken from each bone and ground according to the method described by Frost (1958). After passing through absolute alcohol and xylol they were mounted in DePeX. Altogether 411 histologic sections, 127 from untreated, 75 from GH treated and 209 from cortisol treated animals were investigated.

RESULTS AND DISCUSSION

In the specimens from untreated animals neither on the endosteal nor on the periosteal side was bone formation present on the whole circumference of the bone at the same time. Parts of the circumference showed bone formation and at these places fluorescent bands were visible (Fig. 52).

A possible source of error should be mentioned. Though only 5 injections of OTC have been given 6 fluorescent bands were visible. This can be explained by the observation that during the grinding of sections OTC is dissolved from the bone and is present in the water during grinding and is absorbed to the surface of bone. The same finding can be made in dentine. If a section from a tooth from an animal given no injections of OTC is ground with the aid of equipment previously used for the grinding of sections from animals given OTC a fluorescent band will be found in the boundary between dentine and the pulp chamber. If a section from an animal given no injections of OTC is ground with

Fig. 52. Transverse section from tilted 4 month old normal rat. On endosteal side 5 fluorescent bands 16 days interval. What appears as the 6th band is an artefact.

the use of completely fresh equipment no fluorescent band will be found

It was very soon realised that good quantitative measurement of the rate of lamellar bone formation could not be made. This was because the fluorescent bands did not regularly occur round the whole periphery of the bone with the result that it was not possible to make measurements at corresponding parts of the sections from different animals. It is theoretically possible to overcome this difficulty by making comparisons between untreated and treated periods in the same section at randomly selected points where bone formation occurred during the whole experimental period. But in practice this seemed inconvenient because even if a point was selected and measurements were made along the corresponding radius the rate of apposition during periods of equal length varied widely even in normal animals. Also the variation between different points on the circumference was considerable. It may be possible to make a very great number of measurements in untreated and for example hormone treated animals and then com

Fig. 53 Transverse section from femur 4 month old normal rat. Periosteal side. Five fluorescent bands visible (6 days interval $\times 14$)

pure the quotients between periods of treatment and no treatment but it is very doubtful whether such comparisons would be really informative.

Sections were nevertheless made from bones from the animals in the primary experiments and examined in the hope that it would reveal substantial differences if any between periods of treatment and no treatment. It was found that normal and GH treated animals behaved alike and no certain difference could be detected between them.

In animals given cortisol at most 3 fluorescent bands could be detected. In every one of the untreated and of the GH treated animals 5 bands could always be seen in at least one histologic section from every animal. For purposes of control 3 sections were also taken from the femur and the tibia on the left side of cortisol treated animals (primary experiments) and here too at most 3 fluorescent bands were seen.

The findings were the same in the animals in the control experiments. Normal and GH treated animals behaved alike. Five fluorescent bands were found in at least one histologic section from each animal i.e.

Fig. 1. Transverse section from tibia 4 month old normal rat. Endosteal side. Five fluorescent bands visible (6 days interval) (6th band artefact) 14x

the aid of completely fresh equipment no fluorescent band will be found

It was very soon realised that good quantitative measurement of the rate of lamellar bone formation could not be made. This was because the fluorescent bands did not regularly occur round the whole periphery of the bone with the result that it was not possible to make measurements at corresponding parts of the sections from different animals. It is theoretically possible to overcome this difficulty by making comparisons between untreated and treated periods in the same section at randomly selected points where bone formation occurred during the whole experimental period. But in practice this seemed inconvenient because even if a point was selected and measurements were made along the corresponding radius the rate of apposition during periods of equal length varied widely even in normal animals. Also the variation between different points on the circumference was considerable. It may be possible to make a very great number of measurements in untreated and for example hormone treated animals and then com-

during the preparation of sections. This explanation may perhaps hold for the bone formed on the periosteal side but seems less likely for that on the endosteal side where the last formed bone appears to be more protected. The findings in cortisol treated animals were the same on both the periosteal and endosteal side. To rule out this possible source of error some sections from the left side of animals used in the control experiments were embedded in Ward's Bioplastic and then ground but the finding was the same as in unembedded sections.

The results may be summarised as follows. It is not possible to measure the rate of peri- and endosteal bone apposition in the femur and the tibia in adult rats accurately by performing linear measurements between the fluorescent bands. The short term administration of GH has no certain effect. Administration of very large doses of cortisol seems to result in complete arrest of lamellar bone formation. This last finding parallels the simultaneous retardation of incisor dentine formation.

Concerning this parallelism in mode of reaction it may be mentioned that the rate of longitudinal growth from the proximal growth plate of tibia has been studied in normal solvent treated and GH treated young animals used in the present investigation. GH was found to accelerate this growth highly significantly (Ahlgren & Hansson unpublished observations).

bone formation occurred during the whole experimental period (Figs 53—54). In the animals given cortisol at most 3 bands could be detected on the endosteal and periosteal sides (Fig 55). Animals given solvent for GH or suspension medium for cortisol exhibited the same features as the untreated and the GH treated animals.

The result indicated that during the treatment with cortisol no formation of bone occurred or was so low that the chronologically last 3 fluorescent bands could not be separated. However the last band was not so thick that it could be suspected of consisting of 3 confluent bands (Fig 55). It is also remotely possible that the bands seen were not the ones resulting from the first 3 injections of OTC but from the last injections. In view of the findings in untreated animals this explanation was considered improbable. The most probable explanation is that during treatment with cortisol in very large doses lamellar bone formation completely stops.

One might imagine that during cortisol treatment bone is formed but its mineralisation is so defective that it is very soft and is lost

Fig 55 Transverse section from femur Endosteal side 4 month old rat treated with hydrocortisone. Only 3 fluorescent bands visible (6 days interval 14

is suggested that different types of growth can be described with S shaped curves

Administration of pituitary growth hormone in excess produced a slight but highly significant increase in the rate of apposition of dentine as investigated in adult and young intact female rats

Administration of hydrocortisone in excess produced a highly significant decrease in the rate of dentine apposition as investigated in adult female rats Young cells tended to be less sensitive

In an attempt to compare the rate of formation of dentine with that of lamellar bone in adult female rats it was found that the use of oxytetracycline as a marking agent would not allow precise quantitative determination of the linear rate of formation of periosteal and endosteal lamellar bone A direct numerical comparison between the rate of formation of dentine and of lamellar bone was therefore not possible Both types of tissue were susceptible to hydrocortisone which suppressed the rate of formation of dentine and caused apparently complete cessation of formation of lamellar bone

SUMMARY

In the course of personal preliminary studies of bone healing and lamellar bone formation under the influence of the growth hormone it was thought that dentine might serve as a test tissue for investigations of hormonal influence. The chemical and submicroscopic structure of dentine is similar to that of bone and in normal dentine no resorption occurs.

According to the literature rat incisor dentine normally forms at a constant rate and is very sensitive to influences. Personal preliminary investigations failed to wholly confirm this view. A re-investigation was considered necessary.

Using oxytetracycline as a marking agent a technique was devised for measuring the linear rate of apposition of dentine in different parts of the upper incisors from the apex to the incisal edge and from different places on the circumference. Statistical analysis of the values measured (mostly with the aid of computer) was performed. The rate of incisor dentine apposition varied in a regular but more complicated manner than earlier known. From the apex to the incisal edge of the incisor 3 phases could be recognised: a rising one, a maximum one and a falling one. Studies on female rats of different ages revealed the same general pattern but in young animals the course of events was faster. Based on the results of the computer analysis a technically simpler but not less informative statistical analysis was devised. The "functional age" of the odontoblasts could be related to the rate of apposition of dentine. Young and old cells produced less dentine per unit of time than did those of intermediate age.

The apposition of dentine is briefly compared with other types of growth and with the rate of bone formation in a Haversian system. It

II REVIEW OF LITERATURE

Historical review of literature

In 1845 Purkinie and in 1838 von Luschka gave a detailed description of the disc, its embryology as well as the innervation of the posterior longitudinal ligaments through the sinuvertebral nerve (the nerve of Luschka) Virchow writing in 1872 ascribed afflictions of the vertebral column to asthenia and in 1881 Beneke included asthenia in constitutional disorders Kretschmer in 1907 studied the asthenic weakness of ligaments but finally asthenia was defined as the imperfect development of the connective tissue within the whole organism Schmorl and Junghanns in 1932 in their classic work on the vertebral column have a detailed description of the structure of ligaments The posterior longitudinal ligament they described as narrower and thinner than the anterior longitudinal ligament Schmorl referring to Fick (1904) said that the posterior longitudinal ligament is also more elastic and that on flexion the posterior longitudinal ligament was compressed against the vertebral bodies thus occluding all underlying vascular structures Schmorl in his description of the vessels which enter the posterior aspect of vertebral body mentioned the nerve of Luschka and pointed out that irritation of this nerve could be a cause of pain in the region of the vertebral column

In 1940 Roope using the silver stain method demonstrated unmyelinated nerve endings in the posterior longitudinal ligament The innervation of the posterior longitudinal ligament has also been investigated by Wiberg (1949) Hirsch (1951) Pedersen Blunck and Gardner (1956) Stilwell in 1956 gave a very detailed description of the innervation of the anterior longitudinal ligament in a monkey Magnuson (1944) demonstrated that if one injected physiological saline into the ligament surrounding the intervertebral foramen one may produce pressure on the root ganglia and thus cause pain Hirsch in 1948 and in 1963 injected physiological saline into lumbar discs and reproduced pain characteristic of clinical low back pain Inman and Saunders (1942 1944 and 1947) stressed the role which ligaments play in the mechanics of the spine and considered that low back pain was caused by irritation of the nerves of the longitudinal ligaments

Willis in 1941 considered the various possible causes of low back pain and felt that one of the most important factors was overloading of the longitudinal ligaments This statement was based on congenital deformations of the vertebral column

Haboush in 1947 studied the order in which ligaments tore on forceful flexion of the vertebral column He determined that the posterior longitudinal ligament as well as the lateral portions of the anterior longitudinal ligament burst or tore before the intervertebral discs

I INTRODUCTION

The ligaments of the locomotor system have as their function the joining of the bony elements where they are normally subjected to tension. Their functional prerequisite is that they act as elastic structures. Ageing as well as degenerative changes may alter the mechanical characteristics of ligaments.

For years investigators have speculated on which structures in the lumbar spine may produce low back pain. Many have focused their attention on the discs, others have investigated joints (Lewin 1964) and ligaments of the spine. Tensile properties of interspinous ligaments and of the ligamentum flavum have been tested (Åkerblom 1948, Newman 1952, Silver 1954, Nunley 1958, Rissanen 1960, Rolander 1966, Nachemson and Evans 1967) but there is a lack of information on the physical properties of the anterior and posterior longitudinal ligaments.

In this work the author has endeavoured to answer the following questions:

- a) What are the tensile characteristics of the longitudinal ligaments of the lumbar spine?
- b) Has age any influence on the tensile properties of the longitudinal ligaments?
- c) Have degenerative changes of the lumbar spine any influence on the tensile properties of the longitudinal ligaments?

II REVIEW OF LITERATURE

Historical review of literature

In 1845 Purkinie and in 1858 von Iuschka gave a detailed description of the disc, its embryology as well as the innervation of the posterior longitudinal ligaments through the sinuvertebral nerve (the nerve of Luschka) Virchow writing in 1872 ascribed afflictions of the vertebral column to asthenia and in 1881 Beneke included asthenia in constitutional disorders Kretschmer in 1907 studied the asthenic weakness of ligaments but finally asthenia was defined as the imperfect development of the connective tissue within the whole organism. Schmorl and Junghanns in 1932 in their classic work on the vertebral column have a detailed description of the structure of ligaments The posterior longitudinal ligament they described as narrower and thinner than the anterior longitudinal ligament Schmorl referring to Fick (1904) said that the posterior longitudinal ligament is also more elastic and that on flexion the posterior longitudinal ligament was compressed against the vertebral bodies thus occluding all underlying vascular structures Schmorl in his description of the vessels which enter the posterior aspect of vertebral body mentioned the nerve of Luschka and pointed out that irritation of this nerve could be a cause of pain in the region of the vertebral column

In 1940 Roope using the silver stain method demonstrated unmyelinated nerve endings in the posterior longitudinal ligament The innervation of the posterior longitudinal ligament has also been investigated by Wiberg (1949) Hirsch (1951) Pedersen Blanck and Gardner (1956) Stilwell in 1956 gave a very detailed description of the innervation of the anterior longitudinal ligament in a monkey Magnuson (1944) demonstrated that if one injected physiological saline into the ligament surrounding the intervertebral foramen one may produce pressure on the root ganglia and thus cause pain Hirsch in 1948 and in 1963 injected physiological saline into lumbar discs and reproduced pain characteristic of clinical low back pain Inman and Saunders (1942 1944 and 1947) stressed the role which ligaments play in the mechanics of the spine and considered that low back pain was caused by irritation of the nerves of the longitudinal ligaments

Haboush in 1917 studied the order in which ligaments tore on forceful flexion of the vertebral column He determined that the posterior longitudinal ligament as well as the lateral portions of the anterior longitudinal ligament burst or tore before the interspinous ligaments

I INTRODUCTION

The ligaments of the locomotor system have as their function the joining of the bony elements where they are normally subjected to tension. Their functional prerequisite is that they act as elastic structures. Ageing as well as degenerative changes may alter the mechanical characteristics of ligaments.

For years investigators have speculated on which structures in the lumbar spine may produce low back pain. Many have focused their attention on the discs, others have investigated joints (Lewin 1964) and ligaments of the spine. Tensile properties of interspinous ligaments and of the ligamentum flavum have been tested (Åkerblom 1948, Newman 1952, Silver 1954, Nunley 1958, Rissanen 1960, Rolander 1966, Nachemson and Evans 1967) but there is a lack of information on the physical properties of the anterior and posterior longitudinal ligaments.

In this work the author has endeavoured to answer the following questions:

- a) What are the tensile characteristics of the longitudinal ligaments of the lumbar spine?
- b) Has age any influence on the tensile properties of the longitudinal ligaments?
- c) Have degenerative changes of the lumbar spine any influence on the tensile properties of the longitudinal ligaments?

tissue As a protein it belongs to the group of sclero-proteins and comprises $1/3$ of the protein of a human being Grassman in 1965 gave perhaps the best characterization of collagen as a substance in his opening address at St Andrew's when he stated Collagen indeed is a peaceful protein which is not as active as its prominent brother myosin which is needed to raise the sword Collagen causes no wounds but it heals wounds

Collagen is produced by the fibrocytes which in turn are surrounded closely by the collagen fibres The collagen fibres are built up from amino-acids in the following order glycine proline hydroxyproline glycine (Hall 1965) The hydroxyproline which comprises about 20 per cent of the amino-acids found in collagen is considered to be responsible for the resistance of the collagen fibre to various chemical substances (Gross 1961 Hall 1965) The solubility properties of collagen allow collagen to be divided into three fractions (Harkness 1961 and 1966 S F Jackson 1964) These fractions are

- 1) The saline soluble fraction
- 2) The acid soluble fraction
- 3) The insoluble fraction

The fraction which is saline soluble is the one found in young collagen or in collagen structures with a rapid metabolic turn over e.g. the uterus during pregnancy (Hall 1965) The acid soluble fraction also belongs to young collagen The greatest portion of connective tissue however is made up of the insoluble fraction of collagen which characterizes mature connective tissue (Gallop 1964 Hall 1965 Piez 1966) The soluble fractions of collagen, with ageing undergo a change and become insoluble (Gross 1952 Banga 1966)

The amino acids aggregate to form molecules of collagen which are also known as tropo collagen The molecular weight of collagen is in the region of 350 000 The molecule is 7800 Å in length and about 15 Å in width (Hall 1965 Harkness 1966)

There is a number of theoretical models illustrating the molecular structure of collagen (Gross 1952 Gustavsson 1956 Schmitt and Hodge 1960 Harkness 1961 Ramachandran 1962) The most popular theoretical model is a helix coiled to the left which is comprised of three fractions alfa, beta and gamma and the whole structure in turn is in the form of a superhelix or trihelix, coiled to the right The forces which bind the superhelix together are not fully known The assumption is that there are hydrogen bonds between the alfa, beta and gamma fractions (Hall 1965 Banga 1966) The molecules are joined end to end and in this way give rise to microfibrils which have the same linear orientation and are bound to each other by electrostatic forces (Schmitt and Hodge 1960) Of note however is the fact that the molecules are staggered overlapping each other by one quarter of their length Thus in a 2800 Å section this staggering repeats itself four times approximately 700 Å apart, and is visible in the electron microscope as the dark cross bands The fibrils which are made up of microfibrils are within the

Allbrook in 1957 analyzing the cause of anterior lipping felt that it formed as a result of traction at the attachment of the anterior longitudinal ligament to the vertebral bodies

O Connell in 1951 felt that low back pain may be caused by partial tearing or by stretching of ligaments. The relaxation of ligaments is in O Connell's opinion caused by a hormone produced by the corpus luteum (relaxin) during pregnancy which may be the cause of unremitting low back pain during pregnancy particularly if the woman has to do hard work.

Harris and MacNab (1954) link the degenerative changes in the intervertebral disc with changes taking place in the ligaments particularly the longitudinal ligaments and ligamentum flavum.

Leikkinen, in 1959 in his discussion of disc pathology stated that the posterior longitudinal ligament could be stretched by the bulging nucleus pulposus.

In 1962, Arutynow basing his contentions on observations made at surgery concluded that degenerative changes are not confined to the disc but also involve the posterior longitudinal ligament and the ligamentum flavum.

Cremonese and Tomatis in 1963 stated that nerve impulses which originate from irritation of the posterior longitudinal ligament via the sinuvertebral nerve of Luschka cause in severe cases a protective muscle spasm. This enlarges the intervertebral space on the side of the disc herniation and thus diminishes the force on the disc producing at the same time the so called sciatic scoliosis as well as straightening of the lumbar lordosis.

Roaf in 1960 claimed that he was not able to disrupt the normal anterior longitudinal ligaments on flexion or extension of the lumbar spine as the bone fractured. On the other hand rotation easily damages the ligaments. He felt that degenerative changes have no influence on either the posterior or anterior longitudinal ligaments.

Hackett in 1961 felt that excessive stretching of the ligaments stimulates their sensory nerves which via a sympathetic reflex cause neurovascular disturbances in the region of the bone. This in turn results in decalcification and thus weakens the insertion of other ligaments. In this way a vicious circle is established.

Hirsch (1954 and later) discussed the degeneration and deformation of the disc which causes it to interfere with the longitudinal ligaments and thus irritates their nerves as being a possible cause of pain.

General properties of collagen and ground substance

COLLAGEN

The chief components of ligaments are collagen and ground substance. The physical properties of most ligaments are determined by the collagen component. The collagen is not only the framework of all ligaments but also of all connective

Tensile characteristics of collagenous tissues

The first account of the elastic properties of different human tissue was published by Wertheim in 1847. This investigator noted that the deformation of the tissues was not proportional to the loading. The curve constructed on the basis of load and deformation had the shape of a hyperbola. In addition, Wertheim stated that the curve was described by a second degree equation $Y = ax^2 + bx$. This relationship has since been substantiated by many investigators (Annovazzi 1928, Gratz 1931, Akerblom 1948, Stucke 1950, Dick 1951, Rugby 1964, Viidik 1965—66, Kenedi, Gibson and Daly 1965) but their interpretation of the physical properties differ considerably.

It is generally agreed that ligaments exhibit visco-elastic behaviour. A material is called visco-elastic if its properties are some combination both of a solid and of a fluid (Ferry 1961, Fredrikson 1964, Frost 1967).

If one wishes to utilize a classical model of a visco-elastic structure then biological material seems to fit most closely to the Voigt Kelvin element. This is a material in which the stress is the sum of two parts: one proportional to the strain and the other proportional to the strain rate (Ferry 1961, Fredrikson 1964).

In carrying out the loading of a ligament one obtains a curve in which the toe part is concave in the direction of the load axis. Subsequently the line described becomes less and less concave and approaches a straight line.

When the yield point is reached the curve changes direction into the direction of the strain axis (plastic part). Plastic deformation continues until the breaking point is finally reached.

Many authors are of the opinion that the first part of the curve, the toe part, is dependent on the wavy formation of collagen bundles (Stucke 1950, Rugby 1964, Kenedi et al. 1965, Viidik 1966). The curve becomes less concave under the influence of increasing load and when finally the wavy formation disappears and the collagen fibres have assumed an orientation in the line of stress a straight line is achieved that is the elastic portion of the curve. Dick (1951) and Ridge and Wright (1965), studying the elastic properties of skin, were of the opinion that the toe part is due to the presence of elastin fibres and the remainder of the curve is representative of collagen. The elastic property of collagen is evident in the section of the curve between the toe part and the beginning of the plastic range (Annovazzi 1928, Gratz 1931, Smith 1954, Wright and Rennels 1964). Wright and Rennels (1964) determined that loading a collagen sample to 60—65 per cent (1.8 kg/mm²) of the failure load causes a permanent elongation of the specimen. Gratz (1931) felt that the maximal loading of human fascia lata, before plastic deformation took place, was 1.4 kg/mm. Smith (1954), studying the cruciate ligaments of the rabbit, found that one could attain the elastic behaviour of the tissue by loading it with the weight of the rabbit over a 5 minute period or with

resolution of the electronmicroscope as they have a width of 300—1000 Å (Schmitt et al 1942 Schmitt 1944 Wassermann 1951 Hall 1965) The fibrils in turn are joined to give rise to fibres which are then within the resolution of the ordinary microscope The fibrils appear to be glued to each other by mucopolysaccharides (Banga 1966) The mucopolysaccharides can be removed by heating (about 60—70°C) and then the collagen changes into a mass of randomly coiled fibres (Banga 1966 Harkness 1966 Piez 1966) With age some properties of collagen undergo a change Verzar in 1957 showed that the energy of contraction which the collagen fibres generate under the influence of temperature is directly proportional to their age The older the collagen the greater the energy Banga in 1966 found that young collagen is more extensible and has greater tensile strength than old tissue Gross in 1952 found that collagen fibres in the young are both thinner and shorter than in the mature Kohn and Rollerson (1958) found that young fibres absorb fluid in greater quantities and more rapidly than old collagen Verzar (1957) and S F Jackson (1964) found that during an isotonic contraction older collagen fibres contract more and use up more energy than young ones Jackson considers that the changes which take place in the physical properties of collagen are the result not only of ageing but also of maturation and are the adjustment to greater stresses It has also been established that with ageing the amount of ground substance diminishes in favour of an increase in the thickness of the collagen fibres (Catchpole et al 1951 Sobel and Marmorston 1956 Gersh 1959 Hall 1966) and the ratio of the mucopolysaccharides to collagen (H/C ratio) is inversely proportional to age (Sobel and Marmorston (1956)

GROUND SUBSTANCE

The collagen fibres have a close relationship with the ground substance which is comprised chiefly of mucopolysaccharides It is considered that the mucopolysaccharides are produced either in the fibrocytes or in the mast cells (Catchpole et al 1951 Ragan 1952 Jorpes and Yamashima 1956) Meyer in 1956 classified the mucopolysaccharides into sulphated mucopolysaccharides and nonsulphated mucopolysaccharides To the sulphated mucopolysaccharides belong the following Chondroitin sulphate A B C heparine sulphate keratosulphate To the non sulphated group belong Hyaluronic acid and chondroitin

It is felt that the structure of mucopolysaccharides is in the form of a polymer made up of repeated couplets of two sugars Hyaluronic acid does not branch whereas chondroitin sulphate does branch through the sulphate radical It is known that chondroitin sulphate links with protein The combination of mucopolysaccharides with protein is in the form of large radicals which contain or trap large amounts of water within their domains This in turn influences the physical properties of the connective tissue (Gustavsson 1956 Hall 1965)

Tensile characteristics of collagenous tissues

The first account of the elastic properties of different human tissue was published by Wertheim in 1847. This investigator noted that the deformation of the tissues was not proportional to the loading. The curve constructed on the basis of load and deformation had the shape of a hyperbola. In addition Wertheim stated that the curve was described by a second degree equation $Y = ax^2 + bx$. This relationship has since been substantiated by many investigators (Anno-vazzi 1928, Gratz 1931, Akerblom 1948, Stucke 1950, Dick 1951, Rigby 1964, Viidik 1965—66, Kenedi, Gibson and Daly 1965) but their interpretation of the physical properties differ considerably.

It is generally agreed that ligaments exhibit visco-elastic behaviour. A material is called visco-elastic if its properties are some combination both of a solid and of a fluid (Ferry 1961, Fredrikson 1964, Frost 1967).

If one wishes to utilize a classical model of a visco-elastic structure then biological material seems to fit most closely to the Voigt Kelvin element. This is a material in which the stress is the sum of two parts, one proportional to the strain and the other proportional to the strain rate (Ferry 1961, Fredrikson 1964).

In carrying out the loading of a ligament one obtains a curve in which the toe part is concave in the direction of the load axis. Subsequently the line described becomes less and less concave and approaches a straight line.

When the yield point is reached the curve changes direction into the direction of the strain axis (plastic part). Plastic deformation continues until the breaking point is finally reached.

Many authors are of the opinion that the first part of the curve, the toe part, is dependent on the wavy formation of collagen bundles (Stucke 1950, Rigby 1964, Kenedi et al. 1965, Viidik 1966). The curve becomes less concave under the influence of increasing load and when finally the wavy formation disappears and the collagen fibres have assumed an orientation in the line of stress, a straight line is achieved, that is the elastic portion of the curve. Dick (1951) and Ridge and Wright (1965) studying the elastic properties of skin were of the opinion that the toe part is due to the presence of elastin fibres and the remainder of the curve is representative of collagen. The elastic property of collagen is evident in the section of the curve between the toe part and the beginning of the plastic range (Anno-vazzi 1929, Gratz 1931, Smith 1954, Wright and Rennels 1964). Wright and Rennels (1964) determined that loading a collagen sample to 60–80 per cent (1.8 kg/mm^2) of the failure load causes a permanent elongation of the specimen. Gratz (1931) felt that the maximal loading of human fascia lata before plastic deformation took place was 1.4 kg/mm^2 . Smith (1954) studying the cruciate ligaments of the rabbit found that one could attain the elastic behaviour of the tissue by loading it with the weight of the rabbit over a 5 minute period or with

resolution of the electronmicroscope as they have a width of 500—1000 Å (Schmitt et al 1942 Schmitt 1944 Wassermann 1951 Hall 1965) The fibrils in turn are joined to give rise to fibres which are then within the resolution of the ordinary microscope The fibrils appear to be glued to each other by mucopolysaccharides (Banga 1966) The mucopolysaccharides can be removed by heating (about 60—70°C) and then the collagen changes into a mass of randomly coiled fibres (Banga 1966 Harkness 1966, Piez 1966) With age some properties of collagen undergo a change Verzar in 1957 showed that the energy of contraction which the collagen fibres generate under the influence of temperature is directly proportional to their age The older the collagen the greater the energy Banga in 1966 found that young collagen is more extensible and has greater tensile strength than old tissue Gross in 1952 found that collagen fibres in the young are both thinner and shorter than in the mature Kohn and Rollerson (1958) found that young fibres absorb fluid in greater quantities and more rapidly than old collagen Verzar (1957) and S F Jackson (1964) found that during an isotonic contraction older collagen fibres contract more and use up more energy than young ones Jackson considers that the changes which take place in the physical properties of collagen are the result not only of ageing but also of maturation and are the adjustment to greater stresses It has also been established that with ageing the amount of ground substance diminishes in favour of an increase in the thickness of the collagen fibres (Catchpole et al 1951 Sobel and Marmorston 1956 Gersh 1959 Hall 1966) and the ratio of the mucopolysaccharides to collagen (H/C ratio) is inversely proportional to age (Sobel and Marmorston (1956)

GROUND SUBSTANCE

The collagen fibres have a close relationship with the ground substance which is comprised chiefly of mucopolysaccharides It is considered that the mucopolysaccharides are produced either in the fibrocytes or in the mast cells (Catchpole et al 1951 Ragan 1952 Jorpes and Yamashima 1956) Meyer in 1956 classified the mucopolysaccharides into sulphated mucopolysaccharides and nonsulphated mucopolysaccharides To the sulphated mucopolysaccharides belong the following Chondroitin sulphate A B C heparine sulphate keratosulphate To the non sulphated group belong Hyaluronic acid and chondroitin

It is felt that the structure of mucopolysaccharides is in the form of a polymer made up of repeated couplets of two sugars Hyaluronic acid does not branch whereas chondroitin sulphate does branch through the sulphate radical It is known that chondroitin sulphate links with protein The combination of mucopolysaccharides with protein is in the form of large radicals which contain or trap large amounts of water within their domains This in turn influences the physical properties of the connective tissue (Gustavsson 1956 Hall 1965)

Tensile characteristics of collagenous tissues

The first account of the elastic properties of different human tissue was published by Wertheim in 1847. This investigator noted that the deformation of the tissues was not proportional to the loading. The curve constructed on the basis of load and deformation had the shape of a hyperbola. In addition, Wertheim stated that the curve was described by a second degree equation $Y = ax^2 + bx$. This relationship has since been substantiated by many investigators (Annovazzi 1928, Gratz 1931, Akerblom 1948, Stucke 1950, Dick 1951, Rigby 1964, Vudik 1965—66, Kenedi, Gibson and Daly 1965) but their interpretation of the physical properties differ considerably.

It is generally agreed that ligaments exhibit visco elastic behaviour. A material is called visco elastic if its properties are some combination both of a solid and of a fluid (Ferry 1961, Fredrikson 1964, Frost 1967).

If one wishes to utilize a classical model of a visco-elastic structure then biological material seems to fit most closely to the Voigt Kelvin element. This is a material in which the stress is the sum of two parts, one proportional to the strain and the other proportional to the strain rate (Ferry 1961, Fredrikson 1964).

In carrying out the loading of a ligament one obtains a curve in which the toe part is concave in the direction of the load axis. Subsequently the line described becomes less and less concave and approaches a straight line.

When the yield point is reached the curve changes direction into the direction of the strain axis (plastic part). Plastic deformation continues until the breaking point is finally reached.

Many authors are of the opinion that the first part of the curve, the toe part, is dependent on the wavy formation of collagen bundles (Stucke 1950, Rigby 1964, Kenedi et al. 1965, Vudik 1966). The curve becomes less concave under the influence of increasing load and when finally the wavy formation disappears and the collagen fibres have assumed an orientation in the line of stress, a straight line is achieved that is the elastic portion of the curve. Dick (1951) and Ridge and Wright (1965) studying the elastic properties of skin were of the opinion that the toe part is due to the presence of elastin fibres and the remainder of the curve is representative of collagen. The elastic property of collagen is evident in the section of the curve between the toe part and the beginning of the plastic range (Annovazzi 1928, Gratz 1931, Smith 1954, Wright and Rennels 1964). Wright and Rennels (1964) determined that loading a collagen sample to 60—80 per cent (1.8 Kg.mm²) of the failure load causes a permanent elongation of the specimen. Gratz (1931) felt that the maximal loading of human fascia lata before plastic deformation took place was 1.4 Kg.mm². Smith (1954) studying the cruciate ligaments of the rabbit found that one could attain the elastic behaviour of the tissue by loading it with the weight of the rabbit over a 5 minute period or with

momentary submaximal loads. In biological materials such as the ligaments two time dependent phenomena appear namely the creep and the relaxation phenomenon. The gradual approach to limiting extension (strain) under a constant force (stress) is called creep (Ferry 1961, Fredrikson 1964). The gradual reduction in force (stress) exerted by a body under a fixed amount of compression or extension is called relaxation (Ferry 1961, Fredrikson 1964). Both these phenomena exist in the living tissues and make the testing of the physical properties of ligaments very difficult. The curves which one obtains by consecutive loading of the ligament are not identical (Vridik 1967, Galante 1967).

COLLAGEN IN AGEING

Collagen is a protein which may be described as "old" in that sense that with ageing it undergoes slow changes in its metabolic turn over (Banga 1966). Wertheim (1847) found that the 'stiffness' of tissue increases with age. Anno vazzi (1928) found that ligaments from young animals were more deformable than ligaments of older animals. A similar observation was made by Banga (1966) who described young collagen tissue as more stretchable and more resistant to tearing. Gustavsson (1956) stated that connective tissue of mature animals contained more collagen. Ingelmark (1948) proved that with ageing collagenous tissues lose water regardless of their function. Katzenstein and Fecher (1924) described the ligaments of the human knee as less deformable after the age of 40 years. Curtis (1963) while studying the modulus of elasticity found that ligaments of older people were more rigid particularly under slow rates of straining. Galante (1967) studying the physical properties of the annulus fibrosus showed that there is an age difference in the elastic properties of the annulus. He stated that elongation, residual deformation and energy dissipation decreased progressively until the age of 26 after which they remained practically constant.

The investigators who looked into the problem of ageing of connective tissue used different techniques. Many studies were carried out on the solubility properties of collagen in different substances (Harkness 1961, Hall 1965, Banga 1966). The first one who determined the correlation between contractability of collagen under the influence of temperature and the relationship of this with ageing was Verzar (1957). The contractile property of young and old collagen under the influence of concentrated solutions of urea was studied by Elden (1965). Banga (1966) tried to age collagen on the basis of potassium iodide staining. Kratky, Lauer, Ratzenhofer and Sekora (1962) studied the age dependence of human tendon collagen using X ray diffraction. They found a difference between the X ray diffraction patterns of young and old collagen. Rigby (1964) comparing young and old collagenous tissues investigated their physical properties by determining the strain stress curves, X ray diffraction patterns and shrinkage temperatures. He determined that ligaments of older people have greater resistance to strain. Their X ray diffraction pattern showed less distinct wavy formation and

their shrinkage temperature was higher Sylven Paulson Hirsch and Snellman (1951) studying the properties of the nucleus pulposus by electronmicroscopy found that with ageing the three dimensional lattice gel system containing a dense network of collagen fibrils and amorphous interfibrillar substance irregularly loses the amorphous mucoid material and the fibrils become visible The above authors were of the opinion that this mucoid interfibrillar material contained a large quantity of water The decrease with ageing in the amount of this mucoid material results in a decrease in the water content and thus influences the physical properties of this tissue

POST MORTEM CHANGES

The question of how rapidly the mechanical behaviour of collagen tissues changes post mortem has been of great interest to many investigators and to date the question has remained unresolved Wertheim (1847) investigated tendons nerves and art. ctes of dogs immediately and five days after death He determined that no differences in the tensile properties of the tissues took place Annovazzi (1928) found that the physical properties of the cruciate ligaments of the canine knees change immediately after death and even more so in the next ten hours Gratz (1931) while studying the human fascia lata preserved in physiological saline for 18 hours concluded that it seemed to be essentially alive Kenedi et al (1965) using a bioengineering approach to the study of human skin could not find a noticeable difference in the tensile properties of the skin in vivo or in vitro Vudjak Sandqvist and Magi (1965) on the basis of detailed studies of the cruciate ligaments of the rabbit came to the conclusion that no distinct changes in the tensile characteristics of the tissue occur within the first 96 hours after death The authors concluded that the greatest cause of the change in the tensile properties of the tissue was dehydration

The condition for maintaining the physical properties of the ligaments was preservation of the intact and closed knee joint until the test was performed Hirsch and Galante (1967) tried to determine the loss of water from the moment of death to the time of testing by determining the weight of the intervertebral disc of rabbits immediately after death and after 48 hours They found that the difference between the two groups was not significant It may be however that the change in the physical properties of ligaments takes place almost with the last heart beat and this may in some way change the hydromechanical property of the collagen tissue Thereafter other changes take place really very slowly and depend chiefly on the loss of water

III ANATOMY OF THE LONGITUDINAL LIGAMENTS OF THE HUMAN LUMBAR SPINE

The longitudinal ligaments are situated directly on the posterior and anterior aspects of the vertebral bodies and thus join the adjacent vertebrae (Fig 1). Accurate descriptions of the ligaments if one disregards the old classical anatomical texts were given by Fick (1904) Strasser (1908) Schmorl and Junghanns (1932) Rauber Kopsch (1932), Hirsch and Schajowicz (1952).

ANTERIOR LIGAMENT

The anterior longitudinal ligament constitutes a strong band which covers the anterior aspect of the lumbar spine as well as some of the antero lateral aspect. The ligament has a firm attachment to the vertebral bodies particularly at their edges. The average width of the ligaments, measured during this study in 35 autopsy specimens in the age range 20 to 67 years, was as follows

L5	2 cm
L3	2.5 cm
L2	2.3 cm

These measurements were carried out at the level of the vertebral bodies. At the same levels the average thickness of the ligament was

L5	1.9 mm
L3	2.1 mm
L2	0.9 mm

There is an evident thinning of the anterior longitudinal ligament at the level of the annulus fibrosus. The average thickness of the anterior longitudinal ligament at the level of the L4—5 intervertebral disc was 0.8 mm. The ligament is easily separated from the underlying annulus fibrosus but is connected to it by fibres which are disposed at right angles to the axis of the anterior longitudinal ligament (Schmorl and Junghanns 1932). At the level of L3 and L2 the anterior (i.e. the abdominal) surface of the ligament is usually irregular and there are accessory fibres adjacent to the main portion of the ligament. From L2 upwards the ligament becomes thinner and narrower.

POSTERIOR LIGAMENT

The posterior longitudinal ligament is narrower and weaker than the anterior longitudinal ligament. At the level of L5—S1 it appears as an irregularly developed oval structure which varies from 2—2.25 mm in width. From L5

Fig 1 The longitudinal ligaments of the lumbar spine
 a) Anterior longitudinal ligament
 b) Posterior longitudinal ligament.

upwards the ligament forms a narrow band which widens symmetrically at the level of each disc. The ligament is strongly attached to fibres of the annulus fibrosus and to the edge of the vertebral body but very poorly and in some cases not at all to the posterior aspect of the vertebra. The average widths of the ligament at the different levels are as follows

L5	1.4 cm disc level
L3	1.5
L2	1.1
L5	0.7 cm vertebral body level
L3	0.8
L2	0.6

III ANATOMY OF THE LONGITUDINAL LIGAMENTS OF THE HUMAN LUMBAR SPINE

The longitudinal ligaments are situated directly on the posterior and anterior aspects of the vertebral bodies and thus join the adjacent vertebrae (Fig. 1). Accurate descriptions of the ligaments if one disregards the old classical anatomical texts were given by Fick (1904) Strasser (1908) Schmorl and Junghanns (1932) Rauber Kopsch (1932) Hirsch and Schajowicz (1952).

ANTERIOR LIGAMENT

The anterior longitudinal ligament constitutes a strong band which covers the anterior aspect of the lumbar spine as well as some of the antero lateral aspect. The ligament has a firm attachment to the vertebral bodies particularly at their edges. The average width of the ligaments measured during this study in 35 autopsy specimens in the age range 20 to 67 years was as follows:

L5 2 cm

L3 2.5 cm

L2 2.3 cm

These measurements were carried out at the level of the vertebral bodies. At the same levels the average thickness of the ligament was:

L5 1.9 mm

L3 2.1 mm

L2 0.9 mm

There is an evident thinning of the anterior longitudinal ligament at the level of the annulus fibrosus. The average thickness of the anterior longitudinal ligament at the level of the L4—5 intervertebral disc was 0.8 mm. The ligament is easily separated from the underlying annulus fibrosus but is connected to it by fibres which are disposed at right angles to the axis of the anterior longitudinal ligament (Schmorl and Junghanns 1932). At the level of L3 and L2 the anterior (i.e. the abdominal) surface of the ligament is usually irregular and there are accessory fibres adjacent to the main portion of the ligament. From L2 upwards the ligament becomes thinner and narrower.

POSTERIOR LIGAMENT

The posterior longitudinal ligament is narrower and weaker than the anterior longitudinal ligament. At the level of L5—S1 it appears as an irregularly developed oval structure which varies from 2—2.25 mm in width. From L5

IV MATERIAL AND METHODS

Material

The anterior and posterior longitudinal ligaments were taken from lumbar vertebral columns obtained at post mortem. The studies carried out were based on 74 vertebral columns from which 484 samples were taken. In addition to the ligaments samples of the annulus fibrosus were obtained for histological studies. The specimens were tested within 48 hours of death. The ligaments were taken from the segments S1 to T12 inclusively and occasionally the 12th thoracic segment was included. The annulus fibrosus was sampled from L2 L3 L4 and L5. The condition of the intervertebral disc was assessed on the basis of its macroscopic appearance basing it on the generally accepted criteria (Friberg 1948, Friberg and Hirsch 1949, Virgin 1951, Hirsch and Schajowicz 1952, Ingelmark and Ekholm 1952) which are

Grade 1 The normal disc. The annulus fibrosus and the nucleus pulposus are white without a distinct transition as the fibrous structure of the annulus is not visible.

Grade 2 The visibility of the fibres of the annulus determines the transition zone between the nucleus and the annulus.

Grade 3 Visible fissures in the annulus fibrosus. The border between the nucleus and the annulus is no longer distinct. The nucleus pulposus is rather dry and at times one can see distinct brown staining, the so called brown degeneration.

Grade 4 Marked changes. Tears and sequestrations in the region of the annulus and nucleus and brown degeneration, deformation of the adjacent bone to the annulus in the form of osteophytes.

The anterior longitudinal ligament was removed in the form of a band taken from its mid portion and measuring 2 cm in width. The posterior longitudinal ligament was taken in its entirety with the exception that the segments between L5 and S1 as well as those between T12 and L1 because of their size (the ligament is narrow and thin) were not always suitable for testing. The anterior longitudinal ligament in the segment between L4 and L5 was frequently damaged during autopsy and was not always suitable for testing. In addition, particularly in children, the ligaments in the upper segments were too thin and did not meet our test requirements. These segments of the ligaments were not tested but were used for histological examinations. The ligaments were taken from the level of the disc as well as from the segment overlying the vertebra. Where possible the fragments of the ligaments which were adjacent to the disc were tested separately. Table I lists the specimens tested and Table II shows the number of the different test as well as the numbers of preparations of the ligaments which were used for these tests.

The average thickness of the ligaments are as follows

L5 1.3 mm

L3 1.4 ,

L2 0.9 ,

The posterior longitudinal ligament appears to be best developed at the level L3 and L4 where its average thickness is 1.4 mm. From L2 upwards the ligament thins markedly. Throughout the whole length of the ligament one can note a distinctly thicker middle portion approximately 2.5—4 mm in width. In cross-section the ligament has the form of an ellipse. In the mid portion of each vertebral body the posterior longitudinal ligament covers the vascular foramina (Schmorl and Junghans 1932).

The posterior longitudinal ligament is innervated by branches of the sinuvertebral (or Luschka) nerve. This nerve has fibres which connect the nervus spinalis with the sympathetic ganglia and it enters the intervertebral foramen and divides into ascending and descending branches. It gives branches to the vessels and then enters with them into bone through the vascular foramina. It also supplies the posterior longitudinal ligament and, to some degree the ligamentum flavum. The anterior longitudinal ligament is supplied by branches which come from the sympathetic plexus which is connected with the nervus spinalis (Stulow 1956) (Fig. 2). In contradistinction to other ligaments of the vertebral column in which the nerve endings are superficial the anterior longitudinal ligament has its nerve endings deeply situated in its substance (Hollinshead 1965).

Fig. 2 Innervation of the longitudinal ligaments (after Stulow)

Methods

At first the ligaments were removed with the aid of a dissection microscope (Zeiss) using 15 fold magnification. Experience later showed this to be unnecessary. In addition refinements in the preparation technique of the samples minimized damage to the surface of the preparation. In order to determine the orientation of the collagen bundles in both the anterior and posterior longitudinal ligaments histological studies were carried out. We detected a marked wavy formation but nevertheless the mean orientation of bundles was parallel to the longitudinal axis of the lumbar spine. Histological studies of ligaments placed under a certain amount of tensile stress revealed that the collagen bundles straightened and assumed a relationship parallel with one another. The anterior

longitudinal ligament as well as the posterior were cut into segments which corresponded to the levels of L1 L2 L3 L4 and L5 Thereafter these were put in clamps and were loaded to the point of tearing These studies showed that the ligaments were visco elastic The load-strain curves were typical of a collagenous structure (Vidlik 1966 Galante 1967) It was also possible to conclude that, for comparable tests identical sized samples should be used

PREPARATION OF THE TEST SAMPLE

The ligaments after removal from the vertebral column were cut into segments which corresponded to the levels of the lumbar spine These were then frozen in a carbon dioxide snow stream and were cut on the Jung freezing microtome Special calibration of the microtome allowed us to cut sheets of 0.5 mm thickness During the sectioning the knife of the microtome was so positioned that it was parallel to the direction of the collagen bundles

MEASUREMENTS OF THE THICKNESS OF THE TEST SAMPLE

Great difficulties were encountered in determining the thickness of the test samples because of the visco elastic nature of the tissue At first we tried to measure the frozen samples with a micrometer screw gauge but found that this was very inaccurate as the samples thawed very rapidly and changed in consistency We finally based our measurements on the system introduced by Galante (1967) during his studies of the physical properties of the annulus fibrosus This method consists of a dial displacement gauge with an accuracy of ± 0.01 mm made by the firm Metron This gives measurements of the thickness of the ligament placed between two metal plates The weight of the plates as well as the pressure of the micrometer piston does not exceed 0.13 gm/mm^2 which results in a minimal creep of no more than 0.03 mm If the thickness of the test sample showed a difference greater than 5 per cent from the standard thickness or if the thickness of the test sample was not uniform the sample was discarded

METHOD OF OBTAINING IDENTICAL SAMPLES

In order to obtain identical bands of uniform width from the sheets we at first employed a dissection microscope The samples were cut from the sheet under a 15 fold magnification with the aid of a grid graduated in mm which was placed under the sheet We found that the accuracy which one could obtain in this way was not adequate and in addition the time taken to obtain samples was far too long The sample dried a very significant factor as we found in our later experiments We again made use of an instrument introduced by Galante the so called "stamping press" which employs two types of dies For experiments in which we tried to determine the breaking point, dies with a narrowed central segment were employed For all other determinations dies of size $30 \times 2 \text{ mm}$ were

Fig. 3. Recording equipment (according to Kirsch et al.)

employed. A soft plastic material was placed under the sample which was then stamped with the die. A goniometer attached to the base of a rotating wooden disc allowed us to cut the ligaments parallel to the course of the collagen fibres. The cutting dies were machined out of steel which were subsequently hardened. The cutting edges were sharpened at an angle of 15° . In this way we obtained samples of 30 mm length, occasionally a little shorter, of 0.5 mm in thickness and 2 mm in width. The length of the sample was not critical as the distance between the testing clamps during the test was always 9 mm, the length-width ratio being 4.5:1.

TESTING EQUIPMENT

Two types of testing systems were employed in our tests. In the initial determinations of the whole ligament we employed the Alwetron Electronic Universal Testing Machine T 2000 coupled to an XY recorder unit, Philips Y type. We found, however, that the recording device was inadequate. In all other tests we used the following system: Alwetron T 2000 coupled to a Hewlett Packard Moseley recorder model AM 7001 or AM 7030. In order to determine the accuracy of the recording device we coupled the system with an oscilloscope (Textronix type I AG) equipped with a Polaroid camera (Fig. 3 and 4). The curves obtained with the recorder were compared to those obtained with the oscilloscope and they were found to be identical. In trying to determine the breaking point we employed a 50 kg load cell with a 0.1 per cent accuracy. In the other experiments we used a 1 kg load cell with a 0.05 per cent accuracy. The rate of loading was varied from 0.5 mm/min to 50 mm/min. Most tests were conducted at a strain rate of 5 mm/min.

butterfly screw on the side (Fig 5) The samples were examined with the dissection microscope both while they were being loaded and also after loading The analysis of the load-deformation curves did not show any slipping of the samples and loading of the samples to the point of rupture resulted in the rupture of the ligaments in the free space between the clamps

METHODS OF TESTING

We carried out the following investigations in order to describe the tensile characteristics of the longitudinal ligaments

- a) Determination of the breaking point of segments of ligaments of full dimension as well as samples of identical size
- b) Repetitive loading of samples of identical size
- c) The determination of the preloading point
- d) Determination of the elastic properties of the ligament and their relationship to deformation changes in the lumbar spine the level from which the ligament was taken and the age

Experiments in which the samples were exposed to room air were carried out at a temperature between 19—24°C and at a relative humidity between 60—70 per cent The studies in the high humidity chamber were performed in saturated air at 23—28°C

In the determination of the preloading point specimens were loaded at a rate of 0.5 to 50 mm/min in the range 10—1000 gm.

In the load tests carried out with the samples of identical size we loaded and unloaded the samples successively with 500 gm at 35 second intervals We obtained three significantly differing curves (see page 40) In the studies designed to determine the elastic properties of the ligaments in relation to degenerative changes and age the samples were placed in a high humidity chamber and loaded to 500 gm After one minute we measured the stress relaxation i.e. the decrease in stress at a constant deformation Then after waiting a further three minutes we loaded the sample again After a certain amount of time which was arbitrarily chosen to be one minute the sample was loaded again then immediately unloaded and in this way we obtained curves which showed very small residual deformation The determination was repeated once more to see whether the curves were repeatable and whether all the parameters of the curve were identical In order to determine whether one could rely on the results obtained from the sample we carried out the same test on one or two more samples taken from the same segment of the ligament The results were compared and if the curves did not correlate this particular study of the test sample was discarded and not included for analysis in our material

HIGH HUMIDITY CHAMBER

After preliminary tests on ligaments exposed to air we decided that, in order to minimize the water loss which affects the physical properties of the tissue it would be necessary to provide a high humidity environment. Thus we had a special humidity chamber constructed out of Plexiglass which surrounded that part of the testing machine in which the test sample was placed. This humidity chamber was connected to a 'Defensor' humidifier which can produce 80 m³ of saturated air per hour. This machine raises the relative humidity in the chamber to 100 per cent within 5 minutes. The humidity as well as the temperature of the air within the chamber was measured at the level of the test sample with a hygrometer and a thermometer. Although condensation can sometimes be observed on the chamber walls, experiments (see page 36) have shown that this does not result in up take of water by the sample. A second high humidity chamber which was equipped with a high output humidifier (Defensor) was used during the preparation of samples. The front wall of this chamber was made of glass and this allowed us to prepare the ligaments under visual control with an environmental humidity of 100 per cent. The humidity was measured with a hygrometer (Inor) which was suspended at the level of the preparations. During the transfer of the ligaments from the high humidity chamber to the microtome and from the microtome to the testing machine the ligaments were wrapped in a polyethylene sheet.

CLAMPS

Ligaments have a tendency to slip out of clamps and thus it was necessary to investigate different clamping procedures. After carrying out experiments with a number of clamps we finally adopted a clamp which is closed by means of a

Fig 5 The test clamps

butterfly screw on the side (Fig 5) The samples were examined with the dissection microscope both while they were being loaded and also after loading The analysis of the load-deformation curves did not show any slipping of the samples and loading of the samples to the point of rupture resulted in the rupture of the ligaments in the free space between the clamps

METHODS OF TESTING

We carried out the following investigations in order to describe the tensile characteristics of the longitudinal ligaments

- a) Determination of the breaking point of segments of ligaments of full dimension as well as samples of identical size
- b) Repetitive loading of samples of identical size
- c) The determination of the preloading point
- d) Determination of the elastic properties of the ligament and their relationship to deformation changes in the lumbar spine the level from which the ligament was taken and the age

Experiments in which the samples were exposed to room air were carried out at a temperature between 19—24°C and at a relative humidity between 60—70 per cent. The studies in the high humidity chamber were performed in saturated air at 23—28°C

In the determination of the preloading point specimens were loaded at a rate of 0.5 to 50 mm/min in the range 10—1000 gm

In the load tests carried out with the samples of identical size we loaded and unloaded the samples successively with 500 gm at 35 second intervals We obtained three significantly differing curves (see page 40) In the studies designed to determine the elastic properties of the ligaments in relation to degenerative changes and age the samples were placed in a high humidity chamber and loaded to 500 gm. After one minute we measured the stress relaxation i.e. the decrease in stress at a constant deformation Then after waiting a further three minutes we loaded the sample again After a certain amount of time which was arbitrarily chosen to be one minute the sample was loaded again then immediately unloaded and in this way we obtained curves which showed very small residual deformation The determination was repeated once more to see whether the curves were repeatable and whether all the parameters of the curve were identical In order to determine whether one could rely on the results obtained from the sample we carried out the same test on one or two more samples taken from the same segment of the ligament. The results were compared and if the curves did not correlate this particular study of the test sample was discarded and not included for analysis in our material

HIGH HUMIDITY CHAMBER

After preliminary tests on ligaments exposed to air we decided that in order to minimize the water loss which affects the physical properties of the tissue it would be necessary to provide a high humidity environment. Thus we had a special humidity chamber constructed out of Plexiglass which surrounded that part of the testing machine in which the test sample was placed. This humidity chamber was connected to a Defensor humidifier which can produce 80 m³ of saturated air per hour. This machine raises the relative humidity in the chamber to 100 per cent within 5 minutes. The humidity as well as the temperature of the air within the chamber was measured at the level of the test sample with a hygrometer and a thermometer. Although condensation can sometimes be observed on the chamber walls experiments (see page 36) have shown that this does not result in up take of water by the sample. A second high humidity chamber which was equipped with a high output humidifier (Defensor) was used during the preparation of samples. The front wall of this chamber was made of glass and this allowed us to prepare the ligaments under visual control with an environmental humidity of 100 per cent. The humidity was measured with a hygrometer (Inor) which was suspended at the level of the preparations. During the transfer of the ligaments from the high humidity chamber to the microtome and from the microtome to the testing machine the ligaments were wrapped in a polyethylene sheet.

CLAMPS

Ligaments have a tendency to slip out of clamps and thus it was necessary to investigate different clamping procedures. After carrying out experiments with a number of clamps we finally adopted a clamp which is closed by means of a

Fig 5 The test clamps

and ageing we employed punch cards. On these cards we recorded the results obtained from our curves, radiological examinations as well as histological studies of the disc and of the ligaments before and after loading.

Statistical methods

The statistical methods employed in this work are the following

1. In studying samples exposed to air and samples placed in different solutions sign tests have been performed

2. In comparing samples from anterior and posterior ligaments and in comparing samples from degenerated and non degenerated specimens Student's *t* test has been applied to the differences between measurements from samples that have been considered as paired. This technique has also been employed in the comparison between frozen and control samples and in comparing the sample weights before and after placing them in a high humidity chamber

3. In order to investigate the influence of age and level regression equations have been fitted to the data by means of the method of least squares

4. Graphical illustrations in air exposure experiments and swelling curves are fitted to the computed means but the age dependence graphs are products of the method of least squares

The sign test and *t* test when applied to differences both serve as tools to test whether there are different means in two groups or not. Both methods require every observation in one group to be matched to an observation in the other group

In the air exposure and swelling experiments the observations in the two groups are actually from the same samples before and after treatment and clearly paired. In the other comparisons observations have been considered paired. The *t* test performed on differences from such pairs then shows whether the mean difference should be considered as zero

The sign test does not take into account the value of the difference but only its sign. Under the necessary assumption of differences being normally distributed the *t* test always shows a significant difference between group means if a sign test does (the converse not being true). Consequently when a sign test showed a significant difference the more involved computation work of the *t* test was not performed

The method of least squares is the method of fitting a line to given data so as to minimize the sum of squared deviations from this line e.g. assuming a model

$$Y = C_0 + C_1 X_1 + C_n X_n +$$

determine the coefficients C_0 C_1 C_n

EVALUATION OF THE CURVES

The following parameters were evaluated from the load/deformation curves

The total deformation during loading the residual deformation in the sample and the energy dissipation The deformation was calculated from the curve on the basis of simple measurement and expressed in mm Energy dissipation was calculated with the aid of a planimeter (Amsler accuracy of 1/10th cm²) from the area contained between the loading and the unloading curve The resulting energy loss is calculated in gm mm The failure load of the samples was measured from the graphs and expressed in Kg

HISTOLOGICAL STUDIES

Histological studies were carried out on longitudinal and transverse sections of the anterior and posterior portions of the annulus fibrosus Sections of the anterior and posterior longitudinal ligaments were obtained at the disc level as well as at the level of the vertebral bodies In order to prevent buckling of the ligaments on removal from the spine they were fastened to a rigid base Ligaments which were previously tested by loading were similarly fastened and fixed in 10 per cent formalin After fixation the disc material as well as the sections from the ligaments were treated by standard histological methods and stained with Eosin and hematoxyline In those experiments in which we studied the behaviour of collagen bundles under the influence of different loads we used very thin sections of unstained tissue These ligaments were stretched under the microscope by means of special clamps which were loaded with weights varying from 10—100 gm In subsequent experiments ligaments were stretched in the Alvetron machine to a predetermined load and then compressed between two glass plates before being photographed under the microscope

RADIOLOGICAL EXAMINATIONS

All lumbar spines obtained were X rayed in both the anteroposterior and lateral projections The roentgenograms so obtained were analyzed and graded according to the degeneration For this analysis the disc height and lipping were taken as criteria Occasionally we found spina bifida spondylosis and old fractures in the vertebral bodies The radiological grading was subsequently correlated with the results obtained by histological methods

COLLECTION AND RECORDING OF DATA

All experimental data were tabulated and subsequently analyzed statistically employing standard statistical methods Where data were being collected in order to determine the correlation between the elasticity and the degenerative changes

V DISCUSSION OF METHODS

Water loss of samples exposed to air

In our initial investigations of the tensile properties of the longitudinal ligaments of the lumbar spine we observed that the physical properties of these ligaments could change rapidly with dehydration. When we introduced samples of small dimensions (1 mm² in cross section) this led to an even more rapid change in their physical properties as the rate of water loss was greater. We observed that samples exposed to air for 8 minutes gave different curves from those obtained with fresh tissue. In order to determine the rate and the amount of water loss we carried out the following experiment.

From two lumbar spines (nos 1 & 2 Table I) which were in a high humidity chamber we obtained 14 samples of the following dimensions 20×2×0.5 mm. Each sample was immediately enveloped tightly in polyethylene and stored in this fashion until it was weighed. The samples were weighed on a precision balance (E. Mettler type H 16). These were subsequently exposed to air. During the exposure the relative humidity was 60–70 per cent and the air temperature 20°C. Six samples were weighed at 3 minute intervals during a period of 30 minutes (Table III). Eight samples were weighed at 5, 10 and 30 minutes after initial exposure (Table IV).

To test the hypothesis that there is no effect of exposing the samples to air a sign test was performed. This was applied on the initial weight and on the first weight after exposure to air.

Since every sample in both series has decreased in weight the hypothesis of no effect is rejected in both cases. Water loss of samples is presented graphically (Fig 6).

Fig 6 Loss of weight of samples in air at 64 per cent relative humidity and 20°C temperature

CONCLUSION

The drying of small samples which we employed in the testing of the tensile properties of ligaments takes place very rapidly. During the test procedure prolonged exposure to air at 60—70 per cent relative humidity and 20°C temperature led to a much more significant water loss from the samples.

BEHAVIOUR OF THE ANTERIOR AND POSTERIOR LONGITUDINAL LIGAMENTS IN DIFFERENT SOLUTIONS

In order to find out if the water loss from the samples could be prevented by means of immersion in different solutions such as distilled water, Ringer solution, human plasma and Macrodex we carried out the following experiments:

Fig 7 Swelling curves of samples of anterior and posterior longitudinal ligaments in different solutions.

To test the hypothesis that there is no effect of exposing the samples to air a sign test was performed. This was applied on the initial weight and on the first weight after exposure to air.

Since every sample in both series has decreased in weight the hypothesis of no effect is rejected in both cases. Water loss of samples is presented graphically (Fig. 6).

To test whether there is a significant difference between mean weight at the beginning of the experiment and after three minutes in a particular solution a sign test has been performed

Since every sample in every experiment has increased in weight the sign test shows a significant difference between the weight of the sample before and after placing in the solution

CONCLUSION

There was no difference between the fluid uptake of samples obtained from the anterior longitudinal ligament and from the posterior longitudinal ligament. A significant increase in the weight of the samples takes place after three minutes of immersion in distilled water Ringer solution human plasma or Macrodex.

Distilled water was most rapidly taken up by the samples human plasma and Macrodex showed the lowest uptake (see Fig 7) The fluid uptake was so rapid and so great that storage of ligament samples by wrapping them in gauze previously soaked in some solution could not be employed.

Water loss from samples in the high humidity chamber

The experiments which were carried out in order to determine the water loss from samples exposed to air (at 60—70 per cent relative humidity and 20—24°C) as well as the experiments on the solution uptake of samples led to the conclusion that environmental conditions must be created which would lead to the following

- 1 No water loss from the sample during the test procedure
- 2 No fluid uptake of the sample during the test procedure.

Such environmental conditions can be created if the test is carried out in air which is saturated with water vapour In order to prove that such environmental conditions existed in a high humidity chamber and thus would meet our two test requirements the following experiment was carried out.

From two lumbar spine (Table I nos 3 4) ten samples were obtained from the anterior longitudinal ligament and ten from the posterior longitudinal ligament.

We obtained 48 samples of dimension $20 \times 2 \times 0.5$ mm from four lumbar spines (nos 5, 6, 7, 8, Table I). The samples were divided into two groups of 24: one group consisting of samples taken from the anterior longitudinal ligament and the second group of samples consisting of those taken from the posterior longitudinal ligament. In order to have objective results and not rely on data obtained from one lumbar spine, we then mixed the samples (within the groups anterior and posterior) and divided them into eight groups of six. This gave us four groups each consisting of six samples from the anterior longitudinal ligament and four groups consisting of six of the posterior longitudinal ligament. These units of six we shall refer to as sub-groups. Each sub-group was then tested in the following solutions: Ringer solution, human plasma, Macrodex and distilled water. The experiment was carried out separately on the sub-groups comprising the anterior longitudinal ligament and those comprising the posterior longitudinal ligament. A sample after it was removed from the solution was placed between two sheets of Munktell filter paper no. 3 for five seconds in order to remove the superficial solution and these were subsequently weighed at intervals of 3, 6, 9, 12, 30 and 60 minutes. Immediately after weighing the samples were reimmersed in their respective solutions. The results obtained after three minutes of immersion were analyzed statistically and compared with the initial weight. A graphical correlation was also carried out between the results obtained in samples from the anterior longitudinal ligament and the posterior longitudinal ligament. The fluid uptake of the samples was plotted on a graph which gave us swelling curves (Fig. 7).

(along the longitudinal axis) into two halves. One half was kept in a high humidity chamber whilst the other half was immediately transferred to the Cryo microtome where it was frozen to -60°C with carbon dioxide snow. Subsequently it was taken back to the high humidity chamber and allowed to thaw. The thickness of the corresponding halves was then measured. Once it was established that both halves had the same thickness we obtained two samples from each half. In this way we had two samples from both the frozen and control halves of the anterior longitudinal ligaments at the levels of L5, L4, L3 and L2. From the posterior longitudinal ligaments we were able to get only four samples, two from the level of L3 and two from L4 respectively, as the other levels were not wide enough to allow for sampling. Samples thus obtained were then mechanically tested in a high humidity chamber and the resulting data were compared. The parameters of the load deformation curves from corresponding levels of the lumbar spine were very similar. The curves differed systematically and this was related to the difference in the thickness of the ligament at the different levels of the lumbar spine.

CONCLUSION

Rapid freezing of the ligaments to -60°C with subsequent thawing does not influence the tensile property of these ligaments.

Experiment 2

Using our routine method we prepared six samples from both the anterior and posterior ligaments of a lumbar spine (Table I no. 11). The samples were then tested. In this way we got repeatable curves. Subsequently, without removing the sample from the clamps, it was frozen with the dioxide snow and immediately thawed (the whole manoeuvre took about three minutes to carry out). The sample, together with the clamps, was then reinserted in the test machine and two successive loadings were carried out. The curves thus obtained did not differ from the previous curves.

CONCLUSION

Rapid freezing of ligaments to a temperature of -60°C and subsequent thawing does not influence their tensile properties.

After complete mixing ten of these were placed in the high humidity test chamber and ten in the high humidity preparation chamber. The humidity in these chambers was continuously monitored during these experiments and the environment immediately surrounding the sample was maintained at 100 per cent relative humidity. In the test chamber the temperature was 26°C and in the preparation chamber 24°C. The samples were maintained in each chamber for a period of one hour. After 10 minutes in the test chamber we noticed considerable condensation occurring on the walls of the chamber. We thought that similar condensation could be occurring on the samples which might lead to a subsequent uptake of water. In order to check whether this phenomenon was taking place as well as to determine whether any water loss occurred while the samples were in the humidity chamber all samples were removed after one hour and immediately weighed.

RESULTS

For each sample the weights before and after the experiment were determined and the results were analyzed by means of a *t* test.

For the 20 differences it was found that

$$\text{Mean difference} = 0.000015$$

$$\text{Standard deviation of differences} = 0.000080$$

This yields a *t* value of 0.83 which is obviously not significant.

CONCLUSION

In a high humidity chamber containing air of 100 per cent relative humidity at a temperature of approximately 25°C both water loss and water uptake by the sample can be prevented. The condensation on the walls of the chamber did not lead to a similar condensation on the sample.

Influence of rapid freezing and thawing on the tensile properties of the ligaments

In order to obtain sheets of uniform thickness our material was frozen at a temperature of -60°C. As we felt that this sudden freezing and thawing might influence the physical properties of the longitudinal ligaments we performed the following experiments.

Experiment 1

The anterior and posterior longitudinal ligaments of two lumbar spines (Table I nos 9-10) were prepared in a high humidity chamber. These were then divided into segments corresponding to lumbar levels. Each sample was carefully divided

(along the longitudinal axis) into two halves. One half was kept in a high humidity chamber whilst the other half was immediately transferred to the Cryomicrotome where it was frozen to -60°C with carbon dioxide snow. Subsequently it was taken back to the high humidity chamber and allowed to thaw. The thickness of the corresponding halves was then measured. Once it was established that both halves had the same thickness we obtained two samples from each half. In this way we had two samples from both the frozen and control halves of the anterior longitudinal ligaments at the levels of L₅, L₄, L₃ and L₂. From the posterior longitudinal ligaments we were able to get only four samples, two from the level of L₃ and two from L₄ respectively, as the other levels were not wide enough to allow for sampling. Samples thus obtained were then mechanically tested in a high humidity chamber and the resulting data were compared. The parameters of the load deformation curves from corresponding levels of the lumbar spine were very similar. The curves differed systematically and this was related to the difference in the thickness of the ligament at the different levels of the lumbar spine.

TABLE VI

(Fig. 14 shown \pm S.D.)

	before freezing	after freezing	n	t
Elongation mm	0.59 ± 0.037	0.59 ± 0.037	20	0.68
Residual deformation mm	0.16 ± 0.033	0.16 ± 0.41	20	0.57
Energy dissipation gm. mm	4.18 ± 0.51	4.17 ± 0.49	20	1.0

CONCLUSION

Rapid freezing of the ligaments to -60°C with subsequent thawing does not influence the tensile property of these ligaments.

Experiment 2

Using our routine method we prepared six samples from both the anterior and posterior ligaments of a lumbar spine (Table 1 no. 11). The samples were then tested. In this way we got repeatable curves. Subsequently without removing the sample from the clamps it was frozen with the dioxide snow and immediately thawed (the whole manoeuvre took about three minutes to carry out). The sample together with the clamps was then reinserted in the test machine and two successive loadings were carried out. The curves thus obtained did not differ from the previous curves.

CONCLUSION

Rapid freezing of ligaments to a temperature of -60°C and subsequent thawing does not influence their tensile properties.

After complete mixing ten of these were placed in the high humidity test chamber and ten in the high humidity preparation chamber. The humidity in these chambers was continuously monitored during these experiments and the environment immediately surrounding the sample was maintained at 100 per cent relative humidity. In the test chamber the temperature was 26°C and in the preparation chamber, 24°C. The samples were maintained in each chamber for a period of one hour. After 10 minutes in the test chamber we noticed considerable condensation occurring on the walls of the chamber. We thought that similar condensation could be occurring on the samples which might lead to a subsequent uptake of water. In order to check whether this phenomenon was taking place as well as to determine whether any water loss occurred while the samples were in the humidity chamber all samples were removed after one hour and immediately weighed.

RESULTS

For each sample the weights before and after the experiment were determined and the results were analyzed by means of a *t* test.

For the 20 differences it was found that

$$\text{Mean difference} = 0.000015$$

$$\text{Standard deviation of differences} = 0.000080$$

This yields a *t* value of 0.83 which is obviously not significant.

CONCLUSION

In a high humidity chamber containing air of 100 per cent relative humidity at a temperature of approximately 25°C both water loss and water uptake by the sample can be prevented. The condensation on the walls of the chamber did not lead to a similar condensation on the sample.

Influence of rapid freezing and thawing on the tensile properties of the ligaments

In order to obtain sheets of uniform thickness our material was frozen at a temperature of -60°C. As we felt that this sudden freezing and thawing might influence the physical properties of the longitudinal ligaments we performed the following experiments.

Experiment 1

The anterior and posterior longitudinal ligaments of two lumbar spines (Table 1 nos 9-10) were prepared in a high humidity chamber. These were then divided into segments corresponding to lumbar levels. Each sample was carefully divided

(along the longitudinal axis) into two halves. One half was kept in a high humidity chamber whilst the other half was immediately transferred to the Cryo microtome where it was frozen to -60°C with carbon dioxide snow. Subsequently it was taken back to the high humidity chamber and allowed to thaw. The thickness of the corresponding halves was then measured. Once it was established that both halves had the same thickness we obtained two samples from each half. In this way we had two samples from both the frozen and control halves of the anterior longitudinal ligaments at the levels of L5, L4, L3 and L2. From the posterior longitudinal ligaments we were able to get only four samples, two from the level of L3 and two from L4 respectively, as the other levels were not wide enough to allow for sampling. Samples thus obtained were then mechanically tested in a high humidity chamber and the resulting data were compared. The parameters of the load/deformation curves from corresponding levels of the lumbar spine were very similar. The curves differed systematically and this was related to the difference in the thickness of the ligament at the different levels of the lumbar spine.

TABLE VI

(Fig. 11 & 12 about $\pm 5\%$)

$$\text{Mean difference} = 0.000015$$

$$\text{Standard deviation of differences} = 0.000080$$

This yields a *t* value of 0.83 which is obviously not significant.

CONCLUSION

In a high humidity chamber containing air of 100 per cent relative humidity at a temperature of approximately 25°C both water loss and water uptake by the sample can be prevented. The condensation on the walls of the chamber did not lead to a similar condensation on the sample.

Influence of rapid freezing and thawing on the tensile properties of the ligaments

In order to obtain sheets of uniform thickness our material was frozen at a temperature of -60°C. As we felt that this sudden freezing and thawing might influence the physical properties of the longitudinal ligaments we performed the following experiments.

Experiment 1

The anterior and posterior longitudinal ligaments of two lumbar spines (Table I nos 9-10) were prepared in a high humidity chamber. These were then divided into segments corresponding to lumbar levels. Each sample was carefully divided

Studies on the loading capacity of samples of equal dimensions

From three lumbar spines (Table I nos 66 73 74) we obtained samples of standard dimensions. The samples were wider at their ends (dumb-bell shaped) to facilitate their insertion into the clamps. The significant dimensions were thickness (0.5 mm) and width (2 mm) at the mid section. The distance between the clamps was always 9 mm. The samples were subsequently loaded to failure. Of 30 studies 26 were suitable for analysis (see Table VIII). The remainder either because of slippage from the clamps or tearing at the clamps were considered unsuitable for analysis and were rejected. These experiments were carried out in order to assess the load level to be used in our subsequent experiments on the elastic properties of the ligaments.

VI TENSILE CHARACTERISTICS OF LONGITUDINAL LIGAMENTS

Studies on the loading capacity of ligaments of full dimensions

From three lumbar spines (Table I nos 67, 68, 72) the longitudinal ligaments were obtained. The ligaments were then divided into segments corresponding to the vertebral body or disc levels. These samples were then studied to determine their loading capacity. The clamps were so adjusted that the distance between them was 10 mm. The ligaments were loaded until they tore and a continuous record was made using a Philips XY recorder. Although 22 segments of ligaments were tested only 14 were suitable for analysis. The remainder had to be rejected because the ligaments slipped out of the clamps or tore at the point where they were held in the clamps. The results are shown in table VII.

TABLE VII

No of specimen (Table I)	Age Years	Level	Anterior ligament		Posterior ligament	
			Yield load kg	Failure load kg	Yield load kg	Failure load kg
67	36	L5	50	64	15.5	16
67	36	L4 disc	23	23	—	—
67	36	L3 disc	—	—	10	11
68	36	L5	46	54	—	—
68	36	L4 disc	15	22	18	20
68	36	L3	—	—	22	25
72	58	L5	20	32	20	22
72	58	L4 disc	10	20	15.5	16
72	58	L3 disc	18	21	14	17

CONCLUSION

Because of the difference in the dimensions of the ligaments we obtained results which differed greatly. We could assume that the anterior and posterior longitudinal ligaments are slightly weaker at the level of the disc. It also appears that there is a greater difference between the yield point and the failure point for the anterior longitudinal ligament than for the posterior longitudinal ligament. The posterior longitudinal ligament ruptures almost immediately after the yield point.

c) Third cycle

old spines. The failure loads for a young spine (26 years) were 2.30 Kg for the anterior ligament and 2.12 kg for the posterior ligament whereas for an old spine (64 years) the corresponding values were 1.90 Kg and 1.83 kg respectively. There is no difference between the loading capacity of samples taken from the body and disc levels.

Load tests repeated at 35 second intervals

It is generally known that repeated loading of ligaments, tendons or segments of the annulus fibrosus produces with each repeated loading a more elastic response (Virgin 1951, Rigby 1964, Rolander 1966, Viidik 1966, Galante 1967). In order to determine the effect of repeated loading on the ligaments, all samples were cyclically loaded three times between 0 and 500 gm at 35 second intervals. For these determinations a total of 30 samples of the anterior longitudinal ligament and 33 samples of the posterior longitudinal ligament were prepared from spines nos 13-33. Table I.

RESULTS

The results show that there was a great difference between the curves obtained from each of the three load cycles (Fig 8 a b c). Both the residual deformation and maximum deformation were seen to decrease with each successive load cycle. In order to assist comparison we have forced the mean values of the parameters obtained during the third load cycle to be unity and the following data have resulted:

CONCLUSION

The average failure load of standard samples of the anterior longitudinal ligaments was 2.12 Kg and of the posterior longitudinal ligaments 1.98 Kg. The lowest failure load for the anterior longitudinal ligament was 1.8 Kg and for the posterior 1.7 Kg. From this we concluded that for subsequent experiments a loading of 0.5 Kg should be used which represented about 30 per cent of the failure load of the weakest sample used in the previous analysis and only 25 per cent of the average failure load of both the anterior and posterior longitudinal ligaments. There was an obvious difference between specimens from young and

Fig 8 Load cycling Sample load/deformation curves obtained at 35-second intervals

c) Third cycle

old spines. The failure loads for a young spine (26 years) were 2.30 Kg for the anterior ligament and 2.12 kg for the posterior ligament, whereas for an old spine (64 years) the corresponding values were 1.90 Kg and 1.83 kg respectively. There is no difference between the loading capacity of samples taken from the body and disc levels.

Load tests repeated at 35 second intervals

It is generally known that repeated loading of ligaments, tendons or segments of the annulus fibrosus produces, with each repeated loading, a more elastic response (Virgin 1951, Rigby 1964, Rolander 1966, Vridik 1966, Galante 1967). In order to determine the effect of repeated loading on the ligaments, all samples were cyclically loaded three times between 0 and 500 gm at 35 second intervals. For these determinations a total of 50 samples of the anterior longitudinal ligament and 55 samples of the posterior longitudinal ligament were prepared from spines nos 13—43. Table I.

RESULTS

The results show that there was a great difference between the curves obtained from each of the three load cycles (Fig 8 a, b, c). Both the residual deformation and maximum deformation were seen to decrease with each successive load cycle. In order to assist comparison we have for each of the mean values of the parameters obtained during the third load cycle to be unity and the following data have resulted:

CONCLUSION

The average failure load of standard samples of the anterior longitudinal ligaments was 2.12 Kg and, of the posterior longitudinal ligaments 1.98 kg. The lowest failure load for the anterior longitudinal ligament was 1.8 Kg and for the posterior 1.7 Kg. From this we concluded that for subsequent experiments a loading of 0.5 Kg should be used which represented about 30 per cent of the failure load of the weakest sample used in the previous analysis and only 25 per cent of the average failure load of both the anterior and posterior longitudinal ligaments. There was an obvious difference between specimens from young and

old spines. The failure loads for a young spine (26 years) were 2.30 Kg for the anterior ligament and 2.12 kg for the posterior ligament whereas for an old spine (64 years) the corresponding values were 1.90 Kg and 1.83 Kg respectively. There is no difference between the loading capacity of samples taken from the body and disc levels.

Load tests repeated at 35 second intervals

It is generally known that repeated loading of ligaments, tendons or segments of the annulus fibrosus produces with each repeated loading a more elastic response (Virgin 1951, Rigby 1964, Rolander 1966, Viidik 1966, Galante 1967). In order to determine the effect of repeated loading on the ligaments, all samples were cyclically loaded three times between 0 and 500 gm at 35 second intervals. For these determinations a total of 50 samples of the anterior longitudinal ligament and 55 samples of the posterior longitudinal ligament were prepared from spines nos 13–33. Table I.

RESULTS

The results show that there was a great difference between the curves obtained from each of the three load cycles (Fig 8 a b c). Both the residual deformation and maximum deformation were seen to decrease with each successive load cycle. In order to assist comparison we have forced the mean values of the parameters obtained during the third load cycle to be unity and the following data have resulted:

TABLE IX

Comparison between mean parameters (105 samples)

	1st load cycle	2nd load cycle	3rd load cycle
<i>Deformation</i>			
Anterior	1 865	1 113	1 00
Posterior	1 815	1 107	1 00
<i>Residual deformation</i>			
Anterior	3 501	1 264	1 00
Posterior	3 864	1 242	1 00
<i>Energy dissipation</i>			
Anterior	2 766	1 199	1 00
Posterior	2 824	1 207	1 00

To compare the tensile properties of samples from anterior and posterior ligaments the following analysis was carried out 20 pairs of ligaments were tested each pair comprising a sample from the posterior and anterior ligaments of the same segment The differences between measurements from anterior and posterior samples were calculated These differences were analyzed by means of a t test to investigate whether the mean difference could be considered as zero Such a comparison has been made for maximum deformation residual deformation and energy dissipation for each of the three load cycles

TABLE X
Deformation (mm)

	1st load cycle	2nd load cycle	3rd load cycle
Mean difference between lig ant. and post (paired observ)	0 1640	0 0105	0 0490
Standard error of differences	0 25	0 17	0 18
Computed t value	2 67	0 24	1 01

TABLE XI
Residual deformation (mm)

	1st load cycle	2nd load cycle	3rd load cycle
Mean difference between lig ant. and post (paired observ)	0 1485	0 0815	0 0590
Standard error of differences	0 27	0 09	0 08
Computed t value	2 23	3 39	2 96

TABLE XII
Energy dissipation (gm mm)

	1st load cycle	2nd load cycle	3rd load cycle
Mean difference between lig ant and post (paired observ)	2.1650	0.9700	0.9300
Standard error of differences	3.7	2.0	1.4
Computed t value	2.40	1.88	2.40

CONCLUSION

The results show that there are significant differences between the parameters obtained from the anterior and posterior longitudinal ligaments although these differences decrease in the second and third load cycles

Comparing the mean parameters of each load cycle for the anterior and posterior ligaments showed that there was a similar proportional change between cycles

VII STUDIES TO OBTAIN THE PRELOADING POINT FOR LONGITUDINAL LIGAMENTS OF THE LUMBAR SPINE

Investigation of shrinkage of the ligaments

The parameters which we obtained from repeated load tests led us to doubt if a material which exhibited such significant residual deformation and large energy dissipation could perform a physiological function. For example a residual strain greater than 10 per cent would make the ligament mechanically useless in the living organism. These results and the fact that the ligaments shrank on removal from the spine suggested that a more comprehensive study should be made. A whole series of queries arises but the most obvious is the influence of death on the mechanical properties of the ligaments. At the moment this question can only be answered hypothetically as we are in no position to prove our points. However if we consider the ligament as a visco elastic substance and if we analyze it from a theoretical point of view then within the ligament there must exist a certain fluid pressure during life. This pressure is maintained by means of a complex equilibration system with the pressure within the circulatory system. The moment the heart stops beating and the circulatory pressure drops to zero the system reequilibrates and the internal pressure within the ligament may also drop thus affecting the mechanical properties of the tissue. The fact that a ligament shrinks or shortens immediately after it is obtained from the lumbar spine indicates that this ligaments exists in a state of prestress. To what extent the prestress of the ligament changes with death or preparation is difficult to assess however it is possible to estimate this prestress by performing experiments on fresh autopsy specimens.

Experiment I

Ten randomly selected lumbar spines were tested in the following manner. On the surface of the ligaments at different lumbar levels pairs of points were marked and the distance between each pair of points was then carefully measured. In each segment no attention was paid to the position of the gauge length relative to the disc and vertebral body. The ligaments were then removed from the lumbar spine and the separation of the previously marked points was again measured. In every case the ligaments shortened by a few mm.

VII STUDIES TO OBTAIN THE PRELOADING POINT FOR LONGITUDINAL LIGAMENTS OF THE LUMBAR SPINE

Investigation of shrinkage of the ligaments

The parameters which we obtained from repeated load tests led us to doubt if a material which exhibited such significant residual deformation and large energy dissipation could perform a physiological function. For example a residual strain greater than 10 per cent would make the ligament mechanically useless in the living organism. These results and the fact that the ligaments shrank on removal from the spine suggested that a more comprehensive study should be made. A whole series of queries arises but the most obvious is the influence of death on the mechanical properties of the ligaments. At the moment this question can only be answered hypothetically as we are in no position to prove our points. However if we consider the ligament as a visco elastic substance and if we analyze it from a theoretical point of view then within the ligament there must exist a certain fluid pressure during life. This pressure is maintained by means of a complex equilibration system with the pressure within the circulatory system. The moment the heart stops beating and the circulatory pressure drops to zero the system reequilibrates and the internal pressure within the ligament may also drop thus affecting the mechanical properties of the tissue. The fact that a ligament shrinks or shortens immediately after it is obtained from the lumbar spine indicates that this ligaments exists in a state of prestress. To what extent the prestress of the ligament changes with death or preparation is difficult to assess however it is possible to estimate this prestress by performing experiments on fresh autopsy specimens.

Experiment I

Ten randomly selected lumbar spines were tested in the following manner. On the surface of the ligaments at different lumbar levels pairs of points were marked and the distance between each pair of points was then carefully measured. In each segment no attention was paid to the position of the gauge length relative to the disc and vertebral body. The ligaments were then removed from the lumbar spine and the separation of the previously marked points was again measured. In every case the ligaments shortened by a few mm.

Spec No 0	Lig ant.	30	28	6.6
	Lig post.	30	27	10

CONCLUSION

The average amount of shrinkage obtained on sectioning ligaments at the disc level in normal conditions is the same as the shrinkage at the body vertebra level

Experiment 3

For this experiment lumbar spine no 73 (Table I) was used. This lumbar spine showed no degenerative changes as determined by means of radiological technique and *microscopic* and *macroscopic* examinations. A needle was inserted into the nucleus pulposus between L3—L2 and L4—L3 levels and about 0.3 cm³ of water was injected in each. Employing the intradiscal pressure measuring device of Nachemson it was determined that the intradiscal pressure was raised by the injection of water from its resting pressure of 0.5 kg/cm² to 7 kg/cm² at the level between L3—L2 and 5 kg/cm² at the level between L4—L3. Two points were marked on each ligament corresponding to the discs and vertebral bodies at the above mentioned levels. The distance between these two points was then measured. Subsequently the ligaments were cut and the distance between these points was again measured.

Results: See Table XV

CONCLUSION

The average amount of shrinkage obtained on sectioning ligaments at the disc level in normal conditions is the same as the shrinkage at the body vertebra level

Experiment 3

For this experiment lumbar spine no 73 (Table I) was used. This lumbar spine showed no degenerative changes as determined by means of radiological technique and microscopic and macroscopic examinations. A needle was inserted into the nucleus pulposus between L3—L2 and L4—L3 levels and about 0.3 cm³ of water was injected into each. Employing the intradiscal pressure measuring device of Nachemson it was determined that the intradiscal pressure was raised by the injection of water from its resting pressure of 0.5 kg/cm² to 7 kg/cm² at the level between L3—L2 and 5 kg/cm² at the level between L4—L3. Two points were marked on each ligament corresponding to the discs and vertebral bodies at the above mentioned levels. The distance between these two points was then measured. Subsequently the ligaments were cut and the distance between these points was again measured.

Results See Table XV

Experiment 2

Two lumbar spines were used (nos 42-70 Table I). Two metal wires were inserted into both the anterior and posterior longitudinal ligaments in a direction perpendicular to the longitudinal axis of the fibres. This was done at the disc level of L3-2 and L5-4 and the spines were then X-rayed. The ligaments were sectioned above and below the wires and with the spine and the X-ray tube in the same relative position, a second radiogram was made. From the roentgenograms we obtained the changes in separation of the wires.

Results See Table XIV

TABLE XIV

		Distance between wires		Contraction Per cent
		Before separation mm	After separation mm

	Lig post.	30	27	10

CONCLUSION

The average amount of shrinkage obtained on sectioning ligaments at the disc level in normal conditions is the same as the shrinkage at the body vertebra level

Experiment 3

For this experiment lumbar spine no 73 (Table I) was used. This lumbar spine showed no degenerative changes as determined by means of radiological technique and microscopic and macroscopic examinations. A needle was inserted into the nucleus pulposus between L3—L2 and L4—L3 levels and about 0.3 cm³ of water was injected into each. Employing the intradiscal pressure measuring device of Nachemson it was determined that the intradiscal pressure was raised by the injection of water from its resting pressure of 0.5 kg/cm² to 7 kg/cm² at the level between L3—L2 and 3 kg/cm² at the level between L4—L3. Two points were marked on each ligament corresponding to the discs and vertebral bodies at the above mentioned levels. The distance between these two points was then measured. Subsequently the ligaments were cut and the distance between these points was again measured.

Result. See Table XV

L5 body vert level	25	22	3	12

The shrinkage of the ligaments from segments of this vertebral column where the intradiscal pressure was not artificially raised did not differ from the shrinkage observed in the samples of ligaments studied from segments of other vertebral columns in previous experiments

CONCLUSION

Increase in the intradiscal pressure causes an increase in the prestress of the longitudinal ligaments of the vertebral column

Experiment 4

Specimen no 9 Table I

Using a thick needle and instruments used routinely for the extirpation of the nucleus pulposus the nuclei of the discs L4—L3 and L3—L2 were removed. At a distance of 3 cm two points were marked on both the anterior and posterior longitudinal ligaments at the level of the L3 vertebral body. In addition two points were marked at 2 cm separation on both ligaments between the levels of L4—L3 and L3—L2. The ligaments were then cut and the distance between the points was again measured.

CONCLUSION

Increase in the intradiscal pressure causes an increase in the prestress of the longitudinal ligaments of the vertebral column

TABLE XIV
Samples of equal dimensions (1 mm)

	Average shortening of lig		Corresponding load gm	
	Anterior	Posterior	Anterior	Posterior
Non-degenerated	10.9	13.4	20-25	50-65
Degenerated	7.1	9.0	10-20	45-50

As the above values of preload were determined for small samples of the ligaments approximate calculations of total ligament preload were performed. These calculations based on the average dimensions of the ligaments gave us values for group 1 of 200—250 gm for the anterior longitudinal ligament and 225—350 gm for the posterior longitudinal ligament. Similarly in group 2 150—200 gm for the anterior and 225—250 gm for the posterior longitudinal ligament were the values obtained.

In order to check the above calculations 12 samples of full ligament cross section were loaded to 5 kg. From two lumbar spines (nos 42-44 Table I) 6 samples were obtained from the anterior and 6 from the posterior longitudinal ligaments. (This represented three samples from each of the ligaments of each of the spines.) In one lumbar spine there were no degenerative changes present whereas in the other both macroscopic and microscopic changes were of the order of grades 3 or 4. From the curves obtained during the loading of these samples it was then possible to calculate the average value of force corresponding to 10.9, 13.4, 7.1 and 9.0 per cent strain respectively and these values were as follows:

TABLE VA
Samples of full cross section

	Average shortening of lig		Corresponding load gm	
	Anterior	Posterior	Anterior	Posterior
Non-degenerated	10.9	13.4	180	300
Degenerated	7.1	9.0	120	180

CONCLUSION

The exact determination of the preload value for the longitudinal ligaments is very complicated. Results may differ markedly since the dimensions of the ligaments vary. It is however possible to demonstrate that prestress exists and has a value between 120—350 gm. It appears that the prestress is dependent on the pressure within the nucleus pulposus and on the elasticity of the annulus fibrosus.

CONCLUSION

Decrease in the intradiscal pressure causes a decrease in the preload in the longitudinal ligaments

General conclusions

The above experiments lead to the conclusion that the longitudinal ligaments exist in a prestressed state due to the condition of the intervertebral discs. On removal from the vertebral column the ligaments shrink as they are no longer subjected to this tensile force. The amount of shrinkage or shortening following removal depends on the amount of prestress and this varies with the state of both the intervertebral disc and the annulus fibrosus. In young people in whom the intervertebral disc as well as the annulus fibrosus is intact, the prestress is greater and thus the subsequent shrinkage or shortening is greater. As degenerative changes occur with the concomitant destruction of the intervertebral disc the prestress becomes lower which follows the known reduction in nuclear pressure.

Approximate prestress of the anterior and posterior longitudinal ligaments

Experiments carried out on the shortening of ligaments following their removal from the spine showed that the anterior and posterior longitudinal ligaments did not shorten equally. The anterior longitudinal ligaments shortened less than the posterior. In addition we noted that degenerative changes of the intervertebral disc had a definite bearing on the subsequent shortening of the ligaments. Ligaments obtained from spines without degenerative changes or those of grade 2 degeneration shortened significantly more than those obtained from spines where the intervertebral discs were destroyed.

It was observed that in the group of healthy or slightly degenerated spines the anterior longitudinal ligament shortened following preparation by 10.9 per cent and the posterior by 13.4 per cent. Similarly in the second group that is those with degenerative changes of grade 3 or 4 the anterior longitudinal ligaments shortened by 7.1 per cent and the posterior by 9.0 per cent.

On the curves obtained from loading experiments the loads which corresponded respectively to 10.9, 13.4, 7.1 and 9.0 per cent stretching of the samples were determined (see Table XIX).

TABLE XIX
Samples of equal dimensions (1 mm)

	Average shortening of lig /		Corresponding load gm

On the curves obtained from loading experiments the loads which corresponded respectively to 10.9, 13.4, 7.1 and 9.0 per cent stretching of the samples were determined (see Table XIV).

TABLE XIX
Samples of equal dimensions (1 mm²)

	Average shortening of lig /		Corresponding load gm	
	Anterior	Posterior	Anterior	Posterior
Non-degenerated	10.9	13.4	20-25	30-60
D generated	7.1	9.0	10-20	45-50

As the above values of preload were determined for small samples of the ligaments approximate calculations of total ligament preload were performed. These calculations based on the average dimensions of the ligaments gave us values for group 1 of 200-250 gm for the anterior longitudinal ligament and 225-350 gm for the posterior longitudinal ligament. Similarly in group 2 150-200 gm for the anterior and 225-250 gm for the posterior longitudinal ligament were the values obtained.

In order to check the above calculations 12 samples of full ligament cross section were loaded to 5 kg. From two lumbar spines (nos 42-44 Table I) 6 samples were obtained from the anterior and 6 from the posterior longitudinal ligaments. (This represented three samples from each of the ligaments of each of the spines.) In one lumbar spine there were no degenerative changes present whereas in the other both macroscopic and microscopic changes were of the order of grades 3 or 4. From the curves obtained during the loading of these samples it was then possible to calculate the average value of force corresponding to 10, 13.4, 7.1 and 9.0 per cent strain respectively and these values were as follows:

TABLE XX
Samples of full cross section

	Average shortening of lig		Corresponding load gm	
	Anterior	Posterior	Anterior	Posterior
Non-degenerated	10.9	13.4	180	300
Degenerated	7.1	9.0	120	180

CONCLUSION

The exact determination of the preload value for the longitudinal ligaments is very complicated. Results may differ markedly since the dimensions of the ligaments vary. It is however possible to demonstrate that prestress exists and has a value between 10-350 gm. It appears that the prestress is dependent on the pressure within the nucleus pulposus and on the elasticity of the annulus fibrosus.

VIII MICROSCOPIC INVESTIGATION OF THE LONGITUDINAL LIGAMENTS SUBJECTED TO LOADING

In order to determine what happens to the collagenous fibres of the ligaments during loading the following investigations were made. Samples of 0.05 mm thickness were obtained from both the anterior and posterior longitudinal ligaments (specimen nos 12, 51, 61, Table I). They were placed under a microscope and the following observations were recorded photographically using 100 fold magnification. The samples were subsequently stretched using small hooks arranged in such a way that the loading could be increased by the addition of weights. With each load increment a photograph of the specimen was taken.

It was noted that the collagenous fibres of fully relaxed ligaments were not visible. However, rows of light and dark spots were observed and these appeared to be arranged into regular stripes (Fig 9 a b c d). On initial loading the outlines of the fibres appeared and the light and dark spots began to vanish. With increased loading the outline of the collagenous fibres became more distinct and

Fig 9 Micrographs of the ligament subjected to uniaxial load (x 100)

a/unloaded

b approx 15% failure stress

c/approx 30% failure stress

d/approx 60% failure stress

the light and dark spots vanished completely. As the loading is further increased one could see a distinct reorientation of the fibres into the line of the force. The fibres then began to glide upon one another until the sample tore.

CONCLUSION

It is possible to study under an ordinary microscope collagenous fibres without using stains which change the tensile properties of these fibres. Employing a system which allows for increments in loading one can observe the behaviour of collagenous fibres subjected to increasing load. During loading the collagenous fibres rearrange themselves parallel to the axis of stress. The greater the tensile stress the more complete the rearrangement of the fibres. As the failure load is approached there is a relative gliding of fibres and this represents the breaking of the forces which hold the fibres together. It is only when these forces are broken that the fibres tear completely.

IX STUDY OF THE TENSILE PROPERTIES OF THE LIGAMENTS AS RELATED TO DEGENERATIVE CHANGES, AGE AND LEVEL

The degeneration of the lumbar spine is a common process occurring in adult life. The earliest changes possible to find occur in the discs. Hirsch (1951, 1954), Nachemson (1960), Rolander (1966) and Galante (1967) have demonstrated that changes in the physical properties of the disc are a function of the degenerative process. In order to investigate the influence of degenerative processes and age on the tensile properties of the anterior and posterior longitudinal ligaments the following studies were performed on samples from cadavers 1 day to 67 years of age (Table I nos 34—64).

Effect of degeneration, age and level

206 samples from 30 lumbar spines were investigated.

In order to describe the degree of degeneration the material was graded macroscopically according to the criteria described under 'Materials and Methods' (see page 27). Subsequently the roentgenograms were analyzed and a histological study was made of both the annulus fibrosus and the ligaments. The material was then divided into three groups using the following criteria:

Group 1 Those without degenerative changes.

Group 2 Those with degenerative changes qualifying for group 2 according to macroscopic criteria (see page 19) and without radiographic changes. Histologically degenerative changes such as cavities filled with granulation material and partial cartilagenous metaplasia.

Group 3 Marked degenerative changes visible macroscopically qualifying for group 3 and 4 (see page 19). Radiologically osteophytes as well as narrowing of intervertebral discs. Histologically fissures in the annulus which are filled with vascularized fibrous tissue and pronounced cartilage metaplasia (Hirsch and Schajowicz 1952).

To analyze the tensile properties in samples from non degenerated and degenerated specimens the following computations have been made: 143 non degenerated samples and 63 degenerated samples have been subjected to multiple regression analysis.

This analysis yields an equation of the form

$$Y = C_0 + C_1 A + C_2 A^2 + C_3 L$$

with regression coefficients C_1 , C_2 , C_3 showing the influence of age (A) and level (L).

To detect discrepancies resulting from the linear influence of age a term consisting of the square of A has been put into the model
 The dependent variable Y has been subsequently calculated from values of deformation residual deformation and energy dissipation
 The results are as follows

TABLE XXI

Deformation mm

Non degenerated $Y = 0.64 - \underline{0.0072 A} + \underline{0.00007 A^2} + \underline{0.0259 L}$

Degenerated $Y = 8.68 - \underline{0.26 A} + \underline{0.0002 A^2} + \underline{0.01 L}$

Residual deformation mm

Non degenerated $Y = 0.17 - \underline{0.0018 A} + \underline{0.00001 A^2} + \underline{0.0066 L}$

Degenerated $Y = 1.82 - \underline{0.05 A} + \underline{0.0004 A^2} + \underline{0.005 L}$

Energy dissipation gm mm

Non degenerated $Y = 4.12 - \underline{0.04 A} + \underline{0.0002 A^2} + \underline{0.17 L}$

Degenerated $Y = 35.76 - \underline{1.04 A} + \underline{0.008 A^2} + \underline{0.15 L}$

CONCLUSION

The underlined regression coefficients are significantly different from zero at the 5 per cent level. In the non degenerated material the coefficients for age and level are always significant and the coefficient for A^2 is just significant for deformation.

An analysis of variance for the whole regression model that is comparing the sum of squares due to regression with the sum of squared deviations from the estimated regression equation showed that the variance is significant for every measurement in the non degenerated material but not in the degenerated material. This is due to the spread in the measurements and the fact that a very restricted interval of age was considered.

Effect of degeneration

TABLE XXII

Means and standard errors of the results from degenerated and non degenerated samples in the age range 45—70 years

	Degenerated	Non degenerated
<i>Deformation mm</i>		
Mean	0.46	0.53
S E	0.068	0.076
<i>Residual deformation mm</i>		
Mean	0.12	0.15
S E	0.026	0.024
<i>Energy dissipation gm mm</i>		
Mean	3.11	3.33
S E	0.68	0.61

These are the means and standard errors calculated with no attention paid to differences between anterior and posterior ligaments age or level. They make one suspect that there are differences between degenerated and non degenerated samples. To analyze such a difference six samples from degenerated specimens were selected. These were paired with six samples from the non degenerated material. The purposes of pairing are as follows:

The samples were from specimens of the same age and the same level and the anterior and posterior ligaments corresponded.

For each parameter the differences between the non degenerated samples and the degenerated samples were calculated.

To test whether the mean difference could be considered as zero a t test was performed.

The results of these test procedures are as follows:

TABLE XXIII

	Deformation mm	Residual deformation mm	Energy dissipation gm mm
Mean difference	0.14	0.03	0.6
Standard error of difference	0.07	0.01	0.95
Computed t value	5.12	8.85	1.47

CONCLUSION

Deformation and residual deformation were significantly larger in the non degenerated group of samples. No significant differences were observed in the energy dissipation.

Effect of age

In order to study the influence of age from degenerated samples the mean level has been put into the equations giving the following:

TABLE XXIV

Deformation mm	$Y = 0.73 - 0.0072 A + 0.00007 A^2$
Residual deformation mm	$Y = 0.19 - 0.0018 A + 0.00001 A^2$
Energy dissipation gm mm	$Y = 4.67 - 0.0361 A + 0.00020 A^2$

The regression coefficients are still the same

The equations are illustrated graphically (Fig 10 11 12)

Fig 10 Mean level of total deformation as a function of age Non-degenerated samples

Fig 11 Mean level of residual deformation as a function of age Non-degenerated samples.

	Degenerated	Non degenerated
<i>Deformation mm</i>		
Mean	0 46	0 53
S E	0 068	0 076
<i>Residual deformation mm</i>		
Mean	0 12	0 13
S L	0 026	0 024
<i>Energy dissipation gm mm</i>		
Mean	3 11	3 33
S E	0 68	0 61

These are the means and standard errors calculated with no attention paid to differences between anterior and posterior ligaments age or level. They make one suspect that there are differences between degenerated and non degenerated samples. To analyze such a difference, six samples from degenerated specimens were selected. These were paired with six samples from the non degenerated material. The purposes of pairing are as follows:

The samples were from specimens of the same age and the same level and the anterior and posterior ligaments corresponded.

For each parameter the differences between the non degenerated samples and the degenerated samples were calculated.

To test whether the mean difference could be considered as zero a t test was performed.

The results of these test procedures are as follows:

TABLE XXIII

	Deformation mm	Residual deformation mm	Energy dissipation gm mm
Mean difference	0 14	0 03	0 6
Standard error of difference	0 07	0 01	0 95
Computed t value	5 12	8 85	1 47

CONCLUSION

Deformation and residual deformation were significantly larger in the non degenerated group of samples. No significant differences were observed in the energy dissipation.

Effect of age

In order to study the influence of age from degenerated samples the mean level has been put into the equations giving the following:

X DISCUSSION

The anterior and posterior longitudinal ligaments lie on the anterior and posterior surfaces of the intervertebral discs and are attached to both the discs and the bodies. In view of this relation it is evident that these ligaments will deform with any structural deformation of the disc which can be the result of forces acting on the disc or of structural changes. These ligaments are richly innervated and thus their stimulation may give rise to the sensation of pain (Roofe 1940 Inman and Saunders 1944 Hirsch 1948 Wiberg 1949 Stilwell 1956 Pedersen Blunck and Gardner 1956 Hirsch Ingelmark and Miller 1963 Hollinshead 1965 Jackson Winkelman and Bickel 1966).

The longitudinal ligaments are in a state of prestress as is evidenced by their shrinkage following removal from the spine. This state of prestress is maintained by the conditions of the discs.

A histological study of unstressed ligaments has revealed a wave like configuration of the fibrous components which makes it difficult to distinguish separate fibres. On loading the fibres become progressively polarized and eventually slide upon one another thus causing rupture of the tissue.

During mechanical testing of the ligaments it was observed that the material stabilized in approximately 3 minutes of loading after which time it behaved elastically. This time dependent phenomenon may depend on the fibres and their arrangement and on the properties of the ground substance.

The interrelationship between the disc and the ligaments must be considered both statically and dynamically. If we use certain simplifications in a statical analysis we can consider the relation between the disc and ligaments in two distinct cases, i.e. when the disc faces of the vertebral bodies are parallel or angulated. In order to determine the change in a force acting on a segment of the ligament adjacent to a disc and how this force is dependent on the angle that the adjacent vertebrae form with each other the following system was analyzed (see Fig. 13).

The cartilaginous end plate of L5 was designated A and the cartilaginous end plate of S1 was designated B. The anterior and posterior segments of the ligaments within the limits of the disc were designated a and b respectively and the theoretical analysis was carried out by making the following assumptions:

- 1) That this is a system consisting of the fibres of the ligaments connected to those of the annulus fibrosus which in turn enclose the semi fluid gelatinous substance of the nucleus pulposus.
- 2) That the disc is normal. A force analysis was carried out on the segment between L5 and S1 but such a technique may be employed at all other levels provided the variable angle α , is altered accordingly (see diagram).

Fig 12 Mean level of energy dissipation as a function of age Non-degenerated samples

CONCLUSION

In the young elongation and residual deformation decreased progressively with age After 20—30 years of age changes occur more slowly The rate of change in energy dissipation decreases after the age of 40 years

X DISCUSSION

The anterior and posterior longitudinal ligaments lie on the anterior and posterior surfaces of the intervertebral discs and are attached to both the discs and the bodies. In view of this relation it is evident that these ligaments will deform with any structural deformation of the disc which can be the result of forces acting on the disc or of structural changes. These ligaments are richly innervated and thus their stimulation may give rise to the sensation of pain (Roofe 1940 Inman and Saunders 1944 Hirsch 1948 Wiberg 1949 Stilwell 1956 Pedersen Blunck and Gardner 1956 Hirsch Ingelmark and Miller 1963 Hollinshead 1965 Jackson Winkelman and Bickel 1966).

The longitudinal ligaments are in a state of prestress as is evidenced by their shrinkage following removal from the spine. This state of prestress is maintained by the conditions of the discs.

A histological study of unstressed ligaments has revealed a wave like configuration of the fibrous components which makes it difficult to distinguish separate fibres. On loading the fibres become progressively polarized and eventually slide upon one another thus causing rupture of the tissue.

The interrelationship between the disc and the ligaments must be considered both statically and dynamically. If we use certain simplifications in a statical analysis we can consider the relation between the disc and ligaments in two distinct cases: i.e. when the disc faces of the vertebral bodies are parallel or angulated. In order to determine the change in a force acting on a segment of the ligament adjacent to a disc and how this force is dependent on the angle that the adjacent vertebrae form with each other the following system was analyzed (see Fig. 13).

The cartilaginous end plate of L5 was designated A and the cartilaginous end plate of S1 was designated B. The anterior and posterior segments of the ligaments within the limits of the disc were designated a and b respectively and the theoretical analysis was carried out by making the following assumptions:

- 1) That this is a system consisting of the fibres of the ligaments connected to those of the annulus fibrosus which in turn enclose the semi fluid gelatinous substance of the nucleus pulposus.

- 2) That the disc is normal. A force analysis was carried out on the segment between L5 and S1 but such a technique may be employed at all other levels provided the variable angle α , is altered accordingly (see diagram).

Fig 12 Mean level of energy dissipation as a function of age Non-degenerated samples

CONCLUSION

In the young elongation and residual deformation decreased progressively with age. After 20—30 years of age, changes occur more slowly. The rate of change in energy dissipation decreases after the age of 40 years.

X DISCUSSION

The anterior and posterior longitudinal ligaments lie on the anterior and posterior surfaces of the intervertebral discs and are attached to both the discs and the bodies. In view of this relation it is evident that these ligaments will deform with any structural deformation of the disc which can be the result of forces acting on the disc or of structural changes. These ligaments are richly innervated and thus their stimulation may give rise to the sensation of pain (Roofe 1940, Inman and Saunders 1944, Hirsch 1948, Wiberg 1949, Stulwell 1956, Pedersen, Blunck and Gardner 1956, Hirsch, Ingelmark and Müller 1963, Hollinshead 1963, Jackson, Winkelmann and Bickel 1966).

The longitudinal ligaments are in a state of prestress as is evidenced by their shrinkage following removal from the spine. This state of prestress is maintained by the conditions of the discs.

A histological study of unstressed ligaments has revealed a wave like configuration of the fibrous components which makes it difficult to distinguish separate fibres. On loading the fibres become progressively polarized and eventually slide upon one another thus causing rupture of the tissue.

During mechanical testing of the ligaments it was observed that the material stabilized in approximately 3 minutes of loading after which time it behaved elastically. This time-dependent phenomenon may depend on the fibres and their arrangement and on the properties of the ground substance.

The interrelationship between the disc and the ligaments must be considered both statically and dynamically. If we use certain simplifications in a statical analysis we can consider the relation between the disc and ligaments in two distinct cases, i.e. when the disc faces of the vertebral bodies are parallel or angulated. In order to determine the change in a force acting on a segment of the ligament adjacent to a disc and how this force is dependent on the angle that the adjacent vertebrae form with each other the following system was analyzed (see Fig. 13).

The cartilaginous end plate of L5 was designated A and the cartilaginous end plate of S1 was designated B. The anterior and posterior segments of the ligaments within the limits of the disc were designated a and b respectively and the theoretical analysis was carried out by making the following assumptions:

- 1) That this is a system consisting of the fibres of the ligaments connected to those of the annulus fibrosus which in turn enclose the semi fluid gelatinous substance of the nucleus pulposus.

- 2) That the disc is normal. A force analysis was carried out on the segment between L5 and S1 but such a technique may be employed at all other levels provided the variable angle α , is altered accordingly (see diagram).

Fig 13

Description of theoretical model

We shall assume that the disc is a distorted sphere with a radius R and is loaded from above by the element A which is the surface of the vertebral body exerting a force G at right angles to the surface A . The deformed sphere (disc) rests on the surface B which is the surface of the vertebral body below where surface area is not parallel to A but makes an acute angle α with A . Any force which acts at right angles to the tangent drawn at a point either on the outer or inner surface of the sphere (nucleus pulposus) is transmitted through the outer layer of this sphere. The pressure within the system we shall designate P and the thickness of the wall of the sphere (annulus fibrosus) g . We shall assume that the angle α does not exceed 15° .

In the analysis of this system the force G acting on this sphere and on the element B its support may be resolved into its components N which is perpendicular to the surface B and the tangential component S . These two component forces S and N acting on A produce a shear and compression with respect to B . Disregarding the accuracy of force transmission by the shear on B one can conclude that the stresses in the walls of the container where they come

in contact with the elements A and B will be dependent on the Force S. The magnitude of this force S is $G \sin \alpha$. The force N exerts a pressure on B equal to $G \cos \alpha$. The force N diminishes as the angle α becomes greater. If the two elements A and B are parallel to each other then the angle α is zero and the pressure P is dependent upon the force G and is given by $P = \frac{G}{F}$ where F is the contact area of the element with the sphere.

The stress within the wall is assumed to be $\sigma = \frac{P R}{2g}$ where R is the radius of the wall and g the thickness of the wall. As changes take place in the angle α there is effective a variable angle β of the wall considered to be approximately $\frac{1}{3}$ of the circumference (see diagram). There is a further stress which is

brought about by the force S in this segment as $\sigma_s \approx \frac{S}{g \frac{2}{3} \pi R}$ which is in addition

to the stresses brought about by the pressure P. Although the stress σ_r and σ_θ do not add directly because they act in different directions their combined effect may be expected to be more severe than either one acting alone. In order to obtain numerical values we must then get an average value in every case for the radius R, the thickness of the wall g (annulus fibrosus) as well as the area of contact of the sphere with the vertebral body F.

When the angle α is zero or has a very small value the annulus fibrosus can tolerate a high loading and the ligaments in contact with the annulus are exposed to small tensile stresses. In the lower segments where the angle α is relatively large the tolerance of the annulus is much lower and one can reach the

Fig 13

Description of theoretical model

We shall assume that the disc is a distorted sphere with a radius R and is loaded from above by the element A which is the surface of the vertebral body exerting a force G at right angles to the surface A . The deformed sphere (disc) rests on the surface B which is the surface of the vertebral body below where surface area is not parallel to A but makes an acute angle α with A . XI SUMMARY

The aim of this programme was to investigate *in vitro* the tensile characteristics of the longitudinal ligaments of the human lumbar spine and to determine the influence on these properties of age and degeneration. The material for this work was obtained from 74 lumbar spines taken from cadavers in the age range 1 day to 92 years. In all 484 samples of the longitudinal ligaments were tested.

Preliminary experiments were performed in order to evaluate and develop the proposed experimental techniques.

While preparing ligament samples of standard dimension it was observed that a significant water loss occurred during 3 minutes of exposure to ambient air (60–70 per cent relative humidity and 20–28°C). In an attempt to prevent this dehydration a number of ligament samples were immersed in distilled water, Ringer solution, human plasma or MacroDEX. Within 3 minutes all samples were found to have absorbed a significant amount of fluid, the greatest uptake occurring in distilled water and the least in human blood plasma.

A similar experiment was performed on samples exposed for one hour to water saturated air and no significant change in weight was observed.

In the above experiments there was no significant difference between the behaviour of the anterior and posterior ligaments.

Subsequent experiments were performed in a high humidity chamber containing air at 100 per cent relative humidity and 25–28°C and a similar environment was employed during sample preparation.

In order to obtain samples of ligaments of uniform thickness, sheets from the ligaments were cut on a Cryo-microtome, the ligaments having been frozen to a temperature of –60°C. Investigations showed that rapid freezing and subsequent thawing had no significant effect on the tensile properties. Once the experimental techniques had been established, the test programme proper was initiated.

The first experiment was to determine the failure load of the ligaments and it was observed that the anterior ligament is stronger than the posterior. These results are scattered as the dimensions of ligaments from each lumbar spine showed a considerable variation. In order to obtain comparable results, standard samples of the ligaments (of dimension 0.5 × 2 mm and 9 mm distance between the test clamps) were introduced. Such samples were found to have average failure loads of 2.12 kg and 1.98 kg for the anterior and posterior ligaments respectively and this was independent of the level of the lumbar spine from which the samples were obtained. In samples from severely degenerated spines failure occurred at substantially lower loads. In the investigation of all the other parameters a maximum load of 0.5 kg was employed as this approximates to 30 per cent of the average failure load.

point of rupture much sooner. In this case the ligament is subjected to much higher forces and strains. Once degenerative changes take place the annulus thins and undergoes much greater deformation which causes excessive stretching of the posterior longitudinal ligament. At the moment when the annulus ruptures the above described analysis ceases to hold.

During flexion and extension of the lumbar spine the longitudinal ligaments adjust to the position of the vertebral column and thus either lengthen or shorten. It is probable that the ligaments only work during a certain phase of loading which may be illustrated by the following load/deformation curve (see Fig. 14).

As the disc space decreases the ligaments have to function in the toe part of the curve. When the ligaments are subjected to rapid deformation during movement of the spine then the peak forces induced could be larger than those developed in a wholly elastic material.

XI SUMMARY

The aim of this programme was to investigate "in vitro" the tensile characteristics of the longitudinal ligaments of the human lumbar spine and to determine the influence on these properties of age and degeneration. The material for this work was obtained from 71 lumbar spines taken from cadavers in the age range 1 day to 92 years. In all 484 samples of the longitudinal ligaments were tested.

Preliminary experiments were performed in order to evaluate and develop the proposed experimental techniques.

While preparing ligament samples of standard dimension it was observed that a significant water loss occurred during 3 minutes of exposure to ambient air (60—70 per cent relative humidity and 20—28°C). In an attempt to prevent this dehydration a number of ligament samples were immersed in distilled water, Ringer solution, human plasma or Macroderm. Within 3 minutes all samples were found to have absorbed a significant amount of fluid, the greatest uptake occurring in distilled water and the least in human blood plasma.

A similar experiment was performed on samples exposed for one hour to water saturated air and no significant change in weight was observed.

In the above experiments there was no significant difference between the behaviour of the anterior and posterior ligaments.

Subsequent experiments were performed in a high humidity chamber containing air at 100 per cent relative humidity and 25—28°C and a similar environment was employed during sample preparation.

In order to obtain samples of ligaments of uniform thickness, sheets from the ligaments were cut on a Cryo-microtome, the ligaments having been frozen to a temperature of -60°C. Investigations showed that rapid freezing and subsequent thawing had no significant effect on the tensile properties. Once the experimental techniques had been established, the test programme proper was initiated.

The first experiment was to determine the failure load of the ligaments and it was observed that the anterior ligament is stronger than the posterior. These results are scattered as the dimensions of ligaments from each lumbar spine showed a considerable variation. In order to obtain comparable results, standard samples of the ligaments (of dimension 0.5 × 2 mm and 9 mm distance between the test clamps) were introduced. Such samples were found to have average failure loads of 2.12 kg and 1.98 kg for the anterior and posterior ligaments respectively and this was independent of the level of the lumbar spine from which the samples were obtained. In samples from severely degenerated spines failure occurred at substantially lower loads. In the investigation of all the other parameters a maximum load of 0.5 kg was employed as this approximates to 30 per cent of the average failure load.

point of rupture much sooner. In this case the ligament is subjected to much higher forces and strains. Once degenerative changes take place, the annulus thins and undergoes much greater deformation which causes excessive stretching of the posterior longitudinal ligament. At the moment when the annulus ruptures the above described analysis ceases to hold.

During flexion and extension of the lumbar spine the longitudinal ligaments adjust to the position of the vertebral column and thus either lengthen or shorten. It is probable that the ligaments only work during a certain phase of loading which may be illustrated by the following load/deformation curve (see Fig 14).

As the disc space decreases the ligaments have to function in the toe part of the curve. When the ligaments are subjected to rapid deformation during movement of the spine then the peak forces induced could be larger than those developed in a wholly elastic material.

Subsequent cyclic loading experiments (35 second intervals) were conducted to determine the difference between the tensile properties of the anterior and posterior ligaments as well as the dependence of these properties on the level of the lumbar spine from which the samples were obtained

A statistical analysis of the results obtained from the experiments disclosed the following

There is a significant difference between the tensile properties of the anterior and posterior ligaments. In the second and third load cycles the difference between the deformation of these ligaments is not significant

The tensile properties of both ligaments are dependent on the level of the lumbar spine. The shrinkage of ligaments occurring on separation from the lumbar spine suggested that these ligaments are in a state of prestress and experiments conducted with increased and diminished intradiscal pressure led to the conclusion that this prestress is dependent on the condition of the disc

Values of the prestressing were calculated from experiments performed on samples of standard dimensions and were substantiated by similar experiments on whole ligaments. In non degenerated specimens the preload was 200—250 gm in the anterior ligament and 225—350 gm in the posterior. However in degenerated specimens the values of preload were 120—200 gm and 225—250 gm for the anterior and posterior ligaments respectively

Histological investigation on unstained ligament sections showed that there is a progressive polarization of the collagen fibre bundles with increasing stress. No orderly fibre structure was evident in unstressed samples but with the progressive application of load an increasing proportion of the fibres was reorientated parallel to the axis of stress

The extensibility of both the anterior and posterior ligaments was found to decrease rapidly with ageing but after 20—30 years this progression of stiffening is less marked

Both deformation and residual deformation were significantly smaller in samples obtained from the degenerated spines than in the normal samples

INTRODUCTION

Slipping of the upper femoral epiphysis has at all times offered a difficult orthopedic problem with regard to etiology early diagnosis and choice of treatment. The problem is particularly important because it affects young patients for whom the result of treatment is vital for their later years.

From time to time other names have been used for this disease such as epiphysal fracture adolescent rickets bending of the femoral neck, adolescent or epiphyseal coxa vara arthritis deformans juvenilis and femoral osteochondritis of adolescents.

Pare in 1572 is thought to have been the first to describe slipping of the upper femoral epiphysis (Howorth 1966).

It was not until last century however that positive development in diagnosis began and a growing number of descriptions of cases appeared in the literature. In 1868 Colignon collected all cases presented till then a total of 10.

Bousseau in 1867 at an autopsy was the first to note slipped upper femoral epiphysis in a 1½ year old boy fatally injured by a cart. The autopsy showed a capital epiphysis completely detached from the femur. Wright in 1887 made a further report from an autopsy affecting a 40 year old woman. She had suffered a complete slipping of the capital epiphysis in childhood. Muller in 1888 published 4 cases. In one of these the femoral head had been removed because the lesion was considered tuberculous.

At the end of the 19th century more and more reports appeared each dealing with 3-4 cases. In 1898 Poland published an extensive monograph "Traumatic separation of the epiphysis" containing the cases which had appeared in the literature up to then 31 in all. He added one case of his own. All these published cases had been diagnosed without radiological confirmation on the basis of symptoms the pathological picture of operative or autopsy finding alone. After roentgenography came into use in 1893 more cases were noted and the number of publications increased. However the disease was still considered fairly uncommon since even at the beginning of the century

Harris (1950) published an experimental study of the upper epiphyseal plate of rats tibia. He divided the rats into 3 groups each comprising ten animals. Group 1 consisted of control animals. In group 2 gonadectomy was performed and 1 mg growth hormone administered daily. In the third group oestradiol was given 3 times weekly. It was then observed that the strength needed for detachment of the upper tibial epiphysis of rats treated with growth hormone was only half of that required for detachment of the tibial epiphysis of control animals. In oestradiol treated rats this strength was 50 per cent greater than in control animals and 3 times greater than in rats treated with growth hormone after gonadectomy. For this reason the author concludes that slipped capital epiphysis in adolescents may have two main causes. First that sex hormone secretion is abnormally low as in patients with overweight and underdeveloped genitals and second that growth hormone secretion is abnormally high and growth sudden as clearly appears in tall thin quickly growing children. Obviously in such cases no great importance attaches to the hormone secretion value in itself but to the relation between growth and sex hormone. Thus if sex hormone secretion is very low as in patients with overweight growth hormone secretion may be normal or sub normal but it is abnormally high in relation to sex hormone secretion and may cause weakening of the epiphyseal plate against tangential strain.

Clinical experience, experimental study and endocrinological observation all support the opinion that hormonal factors have a great perhaps decisive influence on the etiology of slipped upper femoral epiphysis. A normal capital epiphysis may of course be detached as a result of powerful trauma but these cases are very rare.

DIAGNOSTIC ASPECTS

Slipped upper femoral epiphysis usually causes pain in the hip and more rarely in the knee. Patients are commonly children aged 9–15. An ordinary antero-posterior X-ray shows slipping of the capital epiphysis as follows.

1. Normally the capital epiphysis protrudes over the upper lateral edge of the neck in the antero-posterior X-ray and appears as a prominence outside the femoral neck. The slightest slipping causes this projection to disappear which is considered by some investigators to be the first symptom (Jerre 1950).

publications dealing with only 1—6 cases appeared. In 1926 Key published 24 cases diagnosed at Massachusetts General Hospital. In 1931 Fergusson and Howorth published 70 cases from New York Orthopedic Hospital over 20 years. Howorth's cases by now number more than 200 (1966).

ETIOLOGY

Opinions on the etiology of slipped upper femoral epiphysis have varied considerably in the course of the centuries. Duvernay (1751) supposed that the condition arose from some other disease such as syphilis or tuberculosis. In the 19th century there was much discussion on the etiology of the disease as the number of cases noted increased. Muller (1888) believed that it was an after effect of rickets, as did Schultz (1892). Trauma was considered an important reason for the origin of slipped upper femoral epiphysis especially as cases previously published were usually a consequence of trauma.

It has been generally recognised, especially during this century, that most cases occur in patients who are at the strongest stage of growth and are somewhat overweight or abnormally tall or both. For this reason it is widely believed that the cause of the disease is an endocrine disturbance. On the other hand, not all cases are bilateral. The number of bilateral cases, however, varies considerably in different reports. Howorth (1957), for instance states that 14 per cent of cases are bilateral, Jerre (1950) 41.8 per cent and Klein et al (1953) 41 per cent. But Billing and Severin (1959) in an extensive monograph based on thorough radiological study have come to the conclusion that bilateral cases or their after effects account for as much as 80 per cent.

Lofgren in 1953 examined 16 cases treated for slipping upper femoral epiphysis with an endocrinological background especially in mind. He observed that in all these cases the sella turcica was abnormally small. His material included 2 pituitary tumors. Also the majority of the male patients had an endocrine defect in the form of overweight. Burrows (1957) also examined the endocrinological background in an extensive study. Urinary ketosteroid secretion was normal. The conclusion was reached from other information and clinical evidence, that one quarter of the boys and almost two thirds of the girls suffered from endocrine disturbance in addition to those who were overweight.

Harris (1950) published an experimental study of the upper epiphyseal plate of rats tibia. He divided the rats into 3 groups each comprising ten animals. Group 1 consisted of control animals. In group 2 gonadectomy was performed and 1 mg growth hormone administered daily. In the third group oestradiol was given 3 times weekly. It was then observed that the strength needed for detachment of the upper tibial epiphysis of rats treated with growth hormone was only half of that required for detachment of the tibial epiphysis of control animals. In oestradiol treated rats this strength was 50 per cent greater than in control animals and 3 times greater than in rats treated with growth hormone after gonadectomy. For this reason the author concludes that slipped capital epiphysis in adolescents may have two main causes. First that sex hormone secretion is abnormally low as in patients with overweight and underdeveloped genitals and second that growth hormone secretion is abnormally high and growth sudden as clearly appears in tall thin quickly growing children. Obviously in such cases no great importance attaches to the hormone secretion value in itself but to the relation between growth and sex hormone. Thus if sex hormone secretion is very low as in patients with overweight growth hormone secretion may be normal or sub normal but it is abnormally high in relation to sex hormone secretion and may cause weakening of the epiphyseal plate against tangential strain.

Clinical experience, experimental study and endocrinological observation all support the opinion that hormonal factors have a great perhaps decisive influence on the etiology of slipped upper femoral epiphysis. A normal capital epiphysis may of course be detached as a result of powerful trauma but these cases are very rare.

DIAGNOSTIC ASPECTS

Slipped upper femoral epiphysis usually causes pain in the hip and more rarely in the knee. Patients are commonly children aged 9–15. An ordinary antero-posterior X ray shows slipping of the capital epiphysis as follows.

1 Normally the capital epiphysis protrudes over the upper lateral edge of the neck in the antero-posterior X ray and appears as a prominence outside the femoral neck. The slightest slipping causes this projection to disappear which is considered by some investigators to be the first symptom (Jerre 1950).

2 When the epiphysis slips backward its thickness (measured from the epiphyseal line to the joint surface) decreases in proportion as the slipping increases

3 Waldenstrom states (1939) that even at an early stage of slipped upper femoral epiphysis the surfaces of the epiphysis and metaphysis become irregular and no longer fit together. In the roentgenogram this is seen as an irregularity of the epiphyseal line

Although in the antero posterior picture slipped epiphysis can thus be diagnosed in some cases, the lateral view is quite indispensable whenever slipped capital epiphysis is suspected. The lateral exposure can be taken in various positions (Billing and Severin 1959). Some maintain that a pre-slipping stage exists in which the epiphyseal line has merely widened and its outlines are obscure (Fergusson and Howorth 1931, Jerre 1950, Howorth 1957 and 1960). The pre-slipping stage, it is stated, produces symptoms with pain in the hip (Fahey et al 1965). Waldenstrom (1939) believes that in such a stage no symptoms are produced and the slipped epiphysis can be detected only from an X-ray picture. Billing and Severin (1959) maintain that slipped epiphysis can be detected at a very early stage as an angle between epiphyseal line and collum which appears in special X-ray exposures.

The degree of slipping of the capital epiphysis in relation to the neck may be expressed in many different ways. In the literature some confusion is caused by the fact that a variety of terms are used. Billing and Severin (1959) express slipping as an angle between epiphyseal line and neck. Some express slipping in inches (Howorth 1957), while others speak only of slight or marked slipping (Jerre 1950). More specific measurements have also been published. Some have divided cases into groups of minimal, quarter, half, three quarter and total slipping (Burrows 1957), others speak of slight, minimal $1/4-1/3$, half $2/3$ (Hall 1957). Newman (1960) classified the position of epiphysis as acceptable or unacceptable. Displacement of the epiphysis has been measured in centimetres by Klein et al (1953). Durbin (1960) considers that when slipping is over half the breadth of the epiphysis i.e. 50 per cent, the prognosis is considerably worse than in milder cases. Most investigators have given up measuring the angle between epiphysis and neck because of uncertain results. The main reason for this uncertainty is that in the X-ray the hip must be in exactly the same position on every occasion which is impossible because of restricted movements in the hip (Jerre 1950). For this reason the displacement is perhaps most exactly expressed as a measure of length or even better as a relative part of the extent of the epiphysis.

TREATMENT

Conservative treatment

Opinions on the relative merits of conservative and operative treatment are somewhat conflicting. Operative treatment which leads to a moderate or poor result may be criticised on the ground that necrosis of the head may not appear in untreated cases and in cases of deformity coxarthrosis does not occur until a later age (Howorth 1957). Conservative treatment may in turn be criticised on the grounds that it is usually prolonged and results are often worse than those produced by operative treatment (Green 1945 Howorth 1949 Jerre 1950).

Conservative treatment mainly involves rest in bed traction walking on crutches walking with the aid of a Thomas splint and plaster immobilisation and a combination of all these.

Jerre in 1950 examined the results of conservative treatment in a follow up and noted that in 21 cases of slight slipping results were good in 76.2 per cent fair in 19 per cent and poor in 4.8 per cent. In 20 cases of greater slipping (marked) 5 per cent of results were good 85 per cent fair and 10 per cent poor. Forrester—Brown (1941) examined 22 cases of conservatively treated slipped epiphysis part of which were treated by traction part by closed reduction and part by walking caliper. Follow up was carried out on 11 patients only one of whom was able to move freely. Nine had abduction adduction and rotation deficiency and all had some degree of flexion deficiency. Howorth (1949) published results on 7 patients who had been treated by traction and then by plaster. In no case was improvement achieved in the position of the epiphysis and results were poor in 6 cases. Durbin (1960) treated 19 cases conservatively and obtained excellent results in 37 per cent good in 37 per cent fair in 5 per cent and poor in 21 per cent. Hall (1957) treated 33 hips conservatively by various methods he states that manipulation produced some change in the position of the epiphysis in 24 cases and no change in 9 cases. The best correction of the position was obtained in cases where a sudden slip had occurred. Capital necrosis occurred in three cases where the condition of the epiphysis had improved it also occurred in two cases where no change had been produced. In Hall's opinion manipulation is justified when performed within a few weeks after sudden slip.

It thus appears that although conservative treatment may achieve partially good results it may also produce necrosis of the head especially if manipulation or prolonged powerful traction is used. Moreover conservative treatment is lengthy and results on the whole do not seem noticeably better than those produced by most methods of operative treatment.

Operative treatment

In operative treatment an important question is whether the position of the capital epiphysis can be accepted or not. If the capital epiphysis has slipped considerably, it may be asked whether the condition can be improved. If the position of the head is acceptable the purpose of operative treatment is to prevent further slipping and several methods of fixing the epiphysis are possible. If the slipping is severe the condition may be accepted even then, and a mere fixation may be considered sufficient, or one may try to improve the position of the head in relation to the neck. A further alternative is to improve the position of the head and neck by performing an osteotomy in the neck or in the subtrochanteric or intertrochanteric part of the femur and fixing the head in its position.

Fixation methods

The upper femoral epiphysis may be fixed to the neck by Smith Petersen nail (Wilson 1938, Wiberg 1941, 1959, Fahey et al 1965, Lindstrom 1958). Other methods are by one or more pegs or screws (Fahey et al 1965, Durbin 1960, Newman 1960, Hall 1957, Hiertonn 1955). Fixation may also be performed by bone pegs (Fergusson and Howorth 1931) or by opening the epiphyseal line and drilling a hole and implanting both cortical bone and cancellous bone (Herndon et al 1963). Good results have been obtained by all these methods. The large nail has been criticised for its tendency to push the loose head forward thus causing necrosis or splitting (Wiberg 1959, Howorth 1957). If, on the other hand, the nail penetrates at some point the joint cartilage and is not noticed or removed, arthrosis may develop sooner than usual (Wiberg 1959, Waldenstrom 1930). For this reason many have advocated the use of thin pins (Moore pins) or screws for fixation (Dunn 1964, Hall 1957).

In Wiberg's material of 185 cases the nail penetrated the joint cartilage in 15 cases, final results were good however, because the position of the nail was corrected in some of the cases. Capital necrosis appeared in two cases, one of which was only partial.

In Lindstrom's series (1959) of 51 nailed hips no case of capital necrosis occurred. Four cases were treated by manipulation followed by nailing and in one of these capital necrosis occurred. In Lindstrom's opinion the Smith Petersen nail is suitable and causes no complications when the slipping is slight.

In Hall's material (1957) of 48 cases treated by Smith Petersen nail 5 cases of capital necrosis occurred but the author attributes them to other causes than the nail. Excellent results were 68.9 per cent with the Smith Petersen nail, 80 per cent with Moore pins. Good results were 18.8 per cent with the Smith Petersen nail, 20 per cent with Moore pins. The latter produced no fair or poor results but the Smith Petersen nail produced 8.4 per cent poor.

Newman (1960) performed fixation in 13 cases with the Smith Petersen nail. One result was poor but the case had been treated for 3 months by traction. In 2 cases subtrochanteric fracture occurred near the nail. In 26 cases stabilisation was performed with Moore pins; in one case the pin came out and re-slipping occurred followed by recovery and consolidation in a bad position.

Durbin (1960) achieved the following results by nailing: excellent 57 per cent, good 22 per cent, fair 14 per cent, poor 7 per cent from a total of 14 hips. 27 hips in his series were fixed with Moore type pins and results were excellent 52 per cent, good 37 per cent, fair 11 per cent and poor nil.

In Jerre's material consisting of 183 hips capital necrosis occurred in 20 cases, only one of which was a result of nailing; however, fifteen were the consequence of reduction and plaster immobilisation and 2 followed closed reduction and nailing. One hundred and two cases were treated with plaster immobilisation.

In Howorth's material of over 200 cases operated by his own method the epiphyseal line failed to close in 4 cases but capital necrosis did not occur in a single instance.

On the basis of the literature alone it appears that Howorth's method as reported by himself produces the best results.

Open reduction and wedge osteotomy

Opinions differ as to when the extent of slipping is such as to necessitate correction of the position of the head. Some maintain that one third of the extent or more causes deformity of the joint later (Hiertonn 1956, Wilson 1938). Others maintain half the extent or more (Durbin 1960) and others 1 cm or more (Klein et al. 1953).

When the epiphysis is considered to have slipped too much by one of the above criteria the method of treatment depends on whether so-called acute slipping or chronic slipping is involved. In the former case closed reduction may be attempted as it is considered that the epiphysis is movable in

Operative treatment

In operative treatment an important question is whether the position of the capital epiphysis can be accepted or not. If the capital epiphysis has slipped considerably, it may be asked whether the condition can be improved. If the position of the head is acceptable the purpose of operative treatment is to prevent further slipping and several methods of fixing the epiphysis are possible. If the slipping is severe the condition may be accepted even then, and a mere fixation may be considered sufficient, or one may try to improve the position of the head in relation to the neck. A further alternative is to improve the position of the head and neck by performing an osteotomy in the neck or in the subtrochanteric or intertrochanteric part of the femur and fixing the head in its position.

Fixation methods

The upper femoral epiphysis may be fixed to the neck by Smith Petersen nail (Wilson 1938, Wiberg 1941, 1959 Fahey et al 1965, Lindstrom 1958). Other methods are by one or more pegs or screws (Fahey et al 1965, Durbin 1960, Newman 1960, Hall 1957, Hierton 1955). Fixation may also be performed by bone pegs (Fergusson and Howorth 1931) or by opening the epiphyseal line and drilling a hole and implanting both cortical bone and cancellous bone (Herndon et al 1963). Good results have been obtained by all these methods. The large nail has been criticised for its tendency to push the loose head forward, thus causing necrosis or splitting (Wiberg 1959, Howorth 1957). If on the other hand the nail penetrates at some point the joint cartilage and is not noticed or removed, arthrosis may develop sooner than usual (Wiberg 1959, Waldenstrom 1930). For this reason many have advocated the use of thin pins (Moore pins) or screws for fixation (Dunn 1964, Hall 1957).

In Wiberg's material of 185 cases the nail penetrated the joint cartilage in 15 cases. Final results were good, however, because the position of the nail was corrected in some of the cases. Capital necrosis appeared in two cases, one of which was only partial.

In Lindstrom's series (1959) of 51 nailed hips no case of capital necrosis occurred. Four cases were treated by manipulation followed by nailing and in one of these capital necrosis occurred. In Lindstrom's opinion the Smith Petersen nail is suitable and causes no complications when the slipping is slight.

Linstrom in 1958 reported 24 wedge osteotomies with 2 caput necrosis 1 traumatic arthritis and 4 coxarthrosis

Other osteotomies

Subtrochanteric osteotomy and intertrochanteric osteotomy are indicated mainly in the late stage of slipped capital epiphysis in order to correct varus and external rotational deformity (Howorth 1966)

ASSESSMENT OF RESULTS

In the assessment of results confusion and difficulty have been caused by the fact that follow up intervals have differed in length methods of treatment have varied greatly and different methods have often been used in the same case Also the division of cases into 'excellent good fair' poor has sometimes been subject to variation

The patient's own assessment is used as first criterion Pain whether at rest or under strain is important Second to be used are results of objective follow up examination most important is the mobility of the hip As a rule mobility is assessed in various directions with points awarded for the degree of mobility attained Methods of calculation available are given by Gade (1947) and Fergusson and Howorth (1931) According to Gade values for a normal hip vary 85—100 points According to Fergusson and Howorth the index for a normal hip should be 80—95 (Fergusson and Howorth 1931 Howorth 1966) In clinical examination attention is also paid to limping discrepancy of length in limbs and the patient's ability to perform various activities (Hall Howorth Newman)

In X ray examination attention is given to the form of the femoral head and the joint surfaces also to possible secondary osteoarthritis or necrosis of the head or its cartilage

very recent slips Results are often unsatisfactory, however, and cases of capital necrosis have occurred (Jerre 1950, Howorth 1966)

For this reason it is the general opinion that closed reduction should not be performed except in very acute cases Results are uncertain even then

Open reduction

In late cases with an unacceptable degree of slip an open reduction or a wedge osteotomy can be performed

Open reduction has been performed since the latter half of last century but has been abandoned in many clinics because of capital necrosis Wilson in 1924 published 7 cases of open reduction 4 of which were fresh and 3 late slipping Fergusson and Howorth in 1931 published 11 cases of open reduction, and Badgley et al in 1948 11 cases, 6 of which produced good results Klein et al in 1948 reported 16 cases and Friberg (1948) 12 cases with one caput necrosis In 1966 Howorth reported 16 cases in which plaster was used after open reduction 5 were good 6 fair and 5 poor Seven were nailed after open reduction and of these 5 were good, 1 fair and 1 poor In the former group there was 1 case of caput necrosis and 7 cases of cartilage necrosis In the latter there were 6 cases of cartilage necrosis and none of caput necrosis Dunn (1964) reported 23 open reductions in which a wedge osteotomy of the neck was performed in the same operation Nineteen of these led to a good result In one case caput necrosis appeared, and in one case partial necrosis after nailing Cartilage necrosis appeared in two cases Open reduction is nowadays considered by some to be unsatisfactory because of the operative risk and technical difficulties (Howorth 1966)

Wedge osteotomy

Howorth in 1966 made a thorough assessment of the literature in which some 400 wedge osteotomies are reported by various authors and caput necrosis recorded in 30 per cent He added his own material of 9 cases after osteotomy 4 of these were immobilised in plaster and 5 with Smith Peter sen nail Results at follow up were good in 5 cases fair in 3 poor in one case Caput necrosis occurred in 2 cases and cartilage necrosis in one

Wiberg in 1955 reported 12 cases only one of which gave rise to caput necrosis the remainder being good In his opinion, however the operation should be limited to rare cases Hierton also in 1955 reported 38 hips operated in the same way there were 5 cases of caput necrosis and 9 of partial caput necrosis Results were good in 24 cases

Table 2
Reason for seeking treatment

Symptoms	Number of patients	Boys	Girls
Pain in hip	35	24	11
Limping	8	4	4
Pain in hip + limping	33	24	9
Pain in knee only	4	3	1
All	80	55	25

32 patients reported injury either immediately before seeking treatment or earlier but in most cases this was a mild one such as slipping on the stairs falling from a bicycle or falling when walking. Only 6 patients sought treatment immediately in the other cases the symptoms were of several months duration. Four patients complained of pain in the knee. In 17 cases the patient had been treated elsewhere either on an incorrect diagnosis or no diagnosis had been reached. In several cases no X-ray had been taken or only an antero-posterior one. In some of these cases no distinct diagnosis had been made. A radiograph taken in a Lauenstein position clearly showed slipped epiphysis in all these 17 cases.

Degree of slipping

In the present material the degree of slipping was estimated as a displacement of the capital epiphysis according to its extent in relation to the femoral neck.

Slipping was estimated always from a lateral X-ray taken in the so-called Lauenstein position. Especially in bilateral cases it was possible to follow the changes in the epiphyseal line of the unaffected hip when the patient came for re-examination of the other hip which had been operated on or treated earlier (Figs 1 and 2). Slipped epiphysis was then diagnosed at a very early stage when displacement was either non-existent or extremely slight (Figs 1, 2, 4). This type of slipped epiphysis was marked as slight. Otherwise slipped epiphysis was classified from the lateral exposure as under 1/3 (Fig 7), under 1/2 (Fig 5 and 6), over half (Figs 8-10, 12 and 13) and complete (Fig 11). When secondary callus had formed in the lower posterior part of the neck between it and the head the degree of slipping was estimated as it had evidently been before callus formation.

P R E S E N T M A T E R I A L

The material comprises all cases of slipped upper femoral epiphysis treated at the Orthopedic Hospital of the Invalid Foundation, Helsinki in the period 1947—1965. This makes a total of 80 patients, 55 boys and 25 girls.

Table 1 shows the distribution of the patients according to the side affected.

Table 1

Side affected

Affected Side	Number of patients	Boys	Girls
Left	41	27	14
Right	20	16	4
Bilat	19	12	7
All	80	55	25

The material contained 21 boys and 8 girls who were clearly overweight. For part of these cases an endocrine defect was clinically evident. One of the boys was also suffering from pituitary tumor and had received radiotherapy. The height of this boy at the time of follow up was 218 cm or 7 ft 3 ins. One girl also had a brain tumor combined with hypopituitarism and one boy a clearly diagnosed endocrine disturbance.

Patients sought treatment for various reasons. Table 2 analyses the symptoms concerned.

Table 2
Reason for seeking treatment

Symptoms	Number of patients	Boys	Girls
Pain in hip	35	24	11
Limping	8	4	4
Pain in hip + limping	33	24	9
Pain in knee only	4	3	1
All	80	55	25

32 patients reported injury either immediately before seeking treatment or earlier but in most cases this was a mild one such as slipping on the stairs falling from a bicycle or falling when walking. Only 6 patients sought treatment immediately in the other cases the symptom were of several months duration. Four patients complained of pain in the knee. In 17 cases the patient had been treated elsewhere either on an incorrect diagnosis or no diagnosis had been reached. In several cases no X ray had been taken or only an antero-posterior one. In some of the cases no distinct diagnosis had been made. A radiograph taken in a Lauenstein position clearly showed slipped epiphysis in all these 17 cases.

Degree of slipping

In the present material the degree of slipping was estimated as a displacement of the capital epiphysis according to its extent in relation to the femoral neck.

Slipping was estimated always from a lateral X ray taken in the so-called Lauenstein position. Especially in bilateral cases it was possible to follow the changes in the epiphyseal line of the unaffected hip when the patient came for re-examination of the other hip which had been operated on or treated earlier (Figs 1 and 2). Slipped epiphysis was then diagnosed at a very early stage when displacement was either non-existent or extremely slight (Figs 1-2-4). This type of slipped epiphysis was marked as slight. Otherwise slipped epiphysis was classified from the lateral exposure as under 1/3 (Fig. 7) under 1/2 (Fig. 5 and 6) over half (Figs 8-10-12 and 13) and complete (Fig. 11). When secondary callus had formed in the lower posterior part of the neck between it and the head the degree of slipping was estimated as it had evidently been before callus formation.

Fig 1 Left hip of a boy aged 14 at the time of nailing of the right hip 29.3.60

A — In the left hip the epiphyseal plate is regular. The patient had no symptoms in this hip. Lateral view on the right. Enlarged view on its right side.

B — Left hip 3 months after A. In the middle of the epiphyseal plate in the lateral view the start of loosening in the form of irregularity. No displacement as yet. The antero posterior view does not show any sign of beginning of slip. The patient did not feel pains in the hip. The enlarged view of the epiphyseal plate on the far right.

C — The patient felt slight pain in the left hip. The antero posterior view is still normal. Roentgenogram taken 5 months after A and 3 months after B. The epiphysis is regular especially in the middle of the lateral view. Slight slip. The epiphysis was fixed by nailing (Fig 4). In this case the patient felt slight pain at the time of the beginning of slipping but in the lateral view signs of this could already be seen before that.

Symptoms and earlier treatment

Table 3 shows duration of symptoms at various degrees of slipping.

Among the bilateral cases were 11 in which slipped epiphysis was detected at an early stage when the patient came for re-examination of a hip that

Table 3

Duration of symptoms

Degree of slipping	Number of hips	Symptoms				Over 1 year
		Under 1 month	1-2 m	2-6 m	6-12 m	
Slight	18	9	0	4	4	1
Under 1/3	26	0	1	11	10	4
Under 1/2	24	4	1	8	5	6
Over 1/2	29	1	0	14	7	7
Complete	2	0	0	1	1	0
All	99	14	2	38	27	18

had been treated earlier. Six of these had pains five did not. Ten cases in which the symptoms had lasted less than 6 months had been in traction earlier. In ten cases with symptoms lasting less than 6 months the slipping had not been diagnosed and one had been given operative treatment elsewhere. The remainder had received no previous treatment. In one case where the symptoms had lasted over a year the patient had been treated for tuberculosis of the hip elsewhere. In 5 cases where the symptoms had lasted over 6 months traction treatment had been given. In 5 cases slipped epiphysis had not been diagnosed. In 2 cases operative treatment had been given. One of these was a case in which open reduction had been attempted elsewhere. The attempt failed and was followed by complete slipping.

The time interval between the slipping in the first affected hip and the slipping in the other hip in bilateral cases is shown in Table 4.

Table 4

Time interval between first and second hip in bilateral cases

Interval between slipping	No Hips	Boys	Girls
Under 1 m	6	4	2
1-2 m.	3	1	2
2-6 m	2	2	0
6-12 m	3	3	0
Over 12 m	5	2	3
All	19	12	7

Fig. 1 Left hip of a boy aged 14 at the time of nailing of the right hip 29.3.60

A — In the left hip the epiphyseal plate is regular. The patient had no symptoms in this hip. Lateral view on the right. Enlarged view on its right side.

B — Left hip 3 months after A ray in A. In the middle of the epiphyseal plate in the lateral view the start of loosening in the form of irregularity. No displacement as yet. The anteroposterior view does not show any sign of beginning of slip. The patient did not feel pains in the hip. The enlarged view of the epiphyseal plate on the far right.

C — The patient felt slight pain in the left hip. The anteroposterior view is still normal. Roentgenogram taken 5 months after A and 3 months after B. The epiphyseal plate is irregular, especially in the middle of the lateral view. Slight slip. The epiphysis was fixed by nailing (Fig. 4). In this case the patient felt slight pain at the time of the beginning of slipping but in the lateral view signs of this could already be seen before that.

Symptoms and earlier treatment

Table 3 shows duration of symptoms at various degrees of slipping.

Among the bilateral cases were 11 in which slipped epiphysis was detected at an early stage when the patient came for re-examination of a hip that

Table 3

Duration of symptoms

Degree of slipping	Number of hips	Symptoms				Over 1 year
		Under 1 month	1-2 m	2-6 m	6-12 m

A

B

Fig 2 Right hip of a boy aged 13 at the time of nailing of the left hip 14 9 60

A — The epiphyseal line is regular except in the middle in the lateral view

B — Three months later after nailing of the other hip and bed rest the irregularity in the middle of the epiphyseal plate has disappeared and the position of the epiphysis is concentric

In 6 cases the interval between slipping in the first and in the second hip was less than 1 month and these were mainly cases in which both hips were operated on within a short period. In one case where the interval was 6 months the patient had been in consultation at our out patient department when right hip had a slip of $1/3$ and the left merely a very slight slip. An operation was not considered necessary and the patient was given crutches and allowed to move with their aid. On the patient's re appearance after six months the slipping had increased, especially on the left side where it had been quite minimal at the earlier visit. Moore pins were used for fixation on the left side. The epiphyseal plate on the right was considered closed.

Table 5 shows treatment received by patients elsewhere before coming to hospital.

Fig. C Three months later The epiphyseal line is more irregular in the lateral X ray than in previous roentgenogram. The patient had no symptoms. The X ray was taken at the same time as the anteroposterior X ray from the other side. D Four months later the fracture is still seen in the lateral X ray. The irregularity of the epiphyseal line is also evident. The patient still felt no pain in this hip. In the anteroposterior X ray the hump in the posterolateral corner has disappeared and eating a slip. E Twelve months later The slip is even more advanced. In the lateral view the protruding epiphyseal line is resorbed and a corresponding amount of secondary callus has formed in the lower part of the neck. In the lateral view The hip was nailed although the boy felt no pain in the hip. In the X ray of the slipping.

Table 5

Treatment before coming to hospital

Previous Treatment	Number of patients	Boys	Girls
No previous treatment	36	26	10
Incorrect diagnosis	17	12	5
Traction treatment	14	7	7
Rest in bed	8	6	2
Other treatment	2	1	1
Operative treatment	3	3	0
All	80	55	25

There were 17 cases of incorrect diagnosis elsewhere 4 of which were bilateral Ten of these patients had been treated on an incorrect diagnosis elsewhere, and 7 had received no treatment before coming to hospital One case had been considered a fracture One case had been mistaken for tuberculosis of the hip one for muscular paralysis and 2 had been treated for muscular sprain One was thought to be the result of excessive growth and not X rayed although there was pain in the hips On arrival at hospital slipping was under 1/3 on both sides In one case nothing was detected despite pain in the hip, but 2 weeks bed rest was prescribed slipping was less than 1/2 In 3 cases the patient was treated as a Calve Legg-Perthes disease by Thomas splint or rest In 36 cases the patient came straight to hospital without previous treatment with a correct diagnosis Other treatment given in this group consisted of Thomas splint in one case and crutches in an other Operative treatment elsewhere consisted of one nailing one wedge osteotomy and one attempted open reduction

Table 6 shows the age of patients on coming for treatment

Table 6

Age at time of operation

Age	Number of patients	Boys	Girls
Under 10 years	1	1	—
10—11 years	1	—	1
11—12 years	11	3	8
12—13 years	15	6	9
13—14 years	16	10	6
14—15 years	11	11	—
Over 15 years	25	24	1
All	80	55	25

At the time of operation the youngest patient was aged 9 years the oldest 37 years. The last mentioned case had a residual stage of the slipped femoral epiphysis and an intertrochanteric osteotomy was performed. Mean age of patients at the time of operation was 14.4 years. Mean age of girls was 12.6 years and that of boys 15.2 years. Six patients had sustained a trauma before admission to hospital. In 4 of these cases the degree of slipping was less than half the extent of the epiphysis in one case over half and in one case the slipping was complete. In the two latter cases a subcapital wedge osteotomy was performed and in one of the cases where the slipping was less than half the extent of the capital epiphysis an open reduction was performed. The others were fixed by nailing or with bone pegs by Howorth's method.

METHODS OF TREATMENT

Of the 80 patients in the present material 19 had a bilateral slip so that the total number of hips treated was therefore 99. The treatment given may be divided roughly into two main groups: conservative and operative. Table 7 shows the number of hips treated conservatively and operatively.

Table 7
Conservative and operative treatment

Degree of slipping	No Hips	Treatment	
		operative	conservative
Slight	18	17	1
Under 1/3	26	22	4
Under 1/2	24	23	1
Over 1/2	29	25	4
Total	2	1	1
All	99	88	11

NON OPERATIVE TREATMENT

Traction and closed reduction

In earlier years traction before operation was considered a routine treatment. In the later years it has not been practised any more. Traction was mentioned as being used only in two cases in this material at our hospital and in 14 cases at another hospital.

Closed reduction was attempted under anaesthesia in 4 cases at another hospital before coming for treatment and in 6 cases closed reduction was attempted at our hospital. The capital epiphysis was fixed in all cases after manipulation. Only in 4 cases of these 10 manipulated cases was the position of the capital epiphysis considered better after closed reduction. All these

4 cases were those in which an obvious recent slipping had taken place. In two cases the closed reduction was performed a few days after sudden exacerbation of pain in the hip in connection of a trauma. Two cases were manipulated in a few weeks after such an accident.

Conservative treatment

The conservative treatment group contains only 4 patients who actually received conservative treatment at our hospital. Six patients had been treated elsewhere or had not been diagnosed and at the moment of consultation were unsuitable for any kind of treatment mostly because of closing of the epiphyseal plate.

One of these was the case in which an open reduction had been attempted while the degree of slipping was less than half the extent of the capital epiphysis. The operation was unsuccessful and resulted in a complete slipping which was not corrected. The patient was sent to our hospital a few years after this operation and the epiphyseal plate was already closed and no further operation was considered indicated. The result was later regarded as poor.

In 3 cases the patient had been treated for an incorrect diagnosis or the slipping had not been diagnosed. One of these had been treated for tuberculosis of the hip for one year with bed rest. The degree of slipping was slight and as the epiphyseal plate had already closed there was no indication for further treatment. The result was good. In one further case the patient had pain in the hip but no radiological examination had been performed. The degree of slipping was in this case more than half the extent of the capital epiphysis and as the epiphyseal plate had closed in this case too no treatment was considered necessary. The hip was stiff at the time of follow up. The third case with an incorrect diagnosis had received no treatment. This was a bilateral slipping in which both epiphyseal plates had closed on arrival at the hospital. One hip was left uncorrected but in the other a subtrochanteric osteotomy was performed. Three further cases were bilateral cases in which one hip had already stabilised so that no treatment was given. The other hips were treated as follows: nailing was performed in one case, open reduction was attempted in one case, wedge osteotomy was performed in one case.

Only four patients were given actual conservative treatment: in one case a Thomas splint was used, in another closed reduction was attempted and the hip immobilised in plaster for 2 months and in two cases the patient was

allowed to move with elbow crutches. The fourth case had attended the out patient department of our hospital, when a slip of $1/3$ was found in one hip and merely a very slight slip in the other. As previously mentioned operative treatment was not considered necessary and the patient was allowed to move with elbow crutches, but when he reappeared at the hospital six months later the slipping had greatly increased especially on the left side, where there was previously only a brightness of the epiphyseal line. The slipping was less than $1/3$ on both sides. The left side was then considered so acute that it was fixed with Moore pins, but on the right side the epiphyseal line was considered to have closed. The slip had not increased in this hip.

OPERATIVE TREATMENT

Table 8 shows to what extent various operative methods were used in varying degrees of slipping.

Table 8

Operative methods

Type of operation	Degree of slipping					
	No Hips	Slight	Under $1/3$	Under $1/2$	Over $1/2$	Complete
Nailing	51	17	20	12	2	—
Howorth	15	—	2	5	8	—
Wedge ost	9	—	—	2	6	1
Intertr or subtr ost	7	—	—	2	5	—
Open reduction	4	—	—	2	2	—
Other oper	2	—	—	—	2	—
All	88	17	22	23	25	1

In earlier years an ordinary Smith Petersen or vitalium nail was used but in the last few years these have been replaced by smaller nails intended for children. Fixation by nailing without reduction was generally performed when the slipping was less than half the extent of the epiphysis. Intertrochanteric and subtrochanteric osteotomy was performed in order to correct position, mainly in the residual stage of the slipping. Other operations consisted of Judet arthroplasty performed after an unsuccessful open reduction in the other case a drilling operation was performed. In recent years nailing and

Howorth operation have become more common at our hospital, while wedge osteotomy and open reduction are no longer performed

After nailing no post operative plaster was used Routine treatment after nailing was as follows during the first 10 days the patient was allowed to get up and use elbow crutches he was allowed full weight bearing on the operated limb only after 2—3 months In the present material 33 patients were in bed for less than one month after nailing also less than a month in bed were 12 patients after Howorth operation one wedge osteotomy one open reduction and one drilling operation The other patients were more than a month in bed most had been operated in previous years when the immobilisation time was longer

FOLLOW UP EXAMINATION

The follow up examination was performed in 1967 The number of patients appearing at the examination was 79 19 were bilateral so that the total number of hips was 98 One patient had died of brain tumor 2 years after operation The shortest period of observation was one year and the longest 19 years with a mean of 6.7 years The youngest patient at follow up was 13 years and the oldest 40 years with a mean age of 21.6 years

allowed to move with elbow crutches. The fourth case had attended the outpatient department of our hospital, when a slip of $1/3$ was found in one hip and merely a very slight slip in the other. As previously mentioned operative treatment was not considered necessary and the patient was allowed to move with elbow crutches, but when he reappeared at the hospital six months later the slipping had greatly increased especially on the left side, where there was previously only a brightness of the epiphyseal line. The slipping was less than $1/3$ on both sides. The left side was then considered so acute that it was fixed with Moore pins but on the right side the epiphyseal line was considered to have closed. The slip had not increased in this hip.

OPERATIVE TREATMENT

Table 8 shows to what extent various operative methods were used in varying degrees of slipping.

Table 8

Operative methods

Type of operation	Degree of slipping					
	No Hips	Slight	Under $1/3$	Under $1/2$	Over $1/2$	Complete
Nailing	51	17	20	12	2	—
Howorth	15	—	2	5	8	—
Wedge ost	9	—	—	2	6	1
Intertr or subtr ost	7	—	—	2	5	—
Open reduction	4	—	—	2	2	—
Other oper	2	—	—	—	2	—
All	88	17	22	23	25	1

In earlier years an ordinary Smith Petersen or vitallium nail was used but in the last few years these have been replaced by smaller nails intended for children. Fixation by nailing without reduction was generally performed when the slipping was less than half the extent of the epiphysis. Intertrochanteric and subtrochanteric osteotomy was performed in order to correct position mainly in the residual stage of the slipping. Other operations consisted of Judet arthroplasty, performed after an unsuccessful open reduction in the other case a drilling operation was performed. In recent years nailing and

The result was considered excellent when the Gade mobility index was 80 or more. In these cases the X ray showed a virtually normal hip and the patient felt no discomfort. In unilateral cases the result was compared with the normal hip. Mobility then had to be at most 10 points under the value estimated for the normal hip.

The result was considered good when the Gade mobility index was 70—80. The patient might have slight pain after strain and the X ray might show slight changes. In order to simplify the comparison of results the excellent and good cases are grouped together in the tables.

The result was considered fair if the mobility index was 50—70. The patient felt pain after strain and the X ray showed moderate changes in the joint surfaces.

The result was considered poor if mobility was 50 or less. In such cases the X ray showed marked changes and the patient might feel pain even after slight strain. In the present material no patient felt sufficient pain to incapacitate him completely. The highest Gade index obtained for a healthy hip in this series was 91.

NON OPERATIVE TREATMENT

Traction

Traction was used in 14 cases at another hospital before coming for treatment and in two cases in this hospital.

In those 14 patients treated with traction elsewhere the degree of slipping was slight in one case, under $1/3$ in 3 cases, under $1/2$ in 3 cases and over $1/2$ in seven cases (Table 10). Of those patients treated with traction at our hospital the degree of slipping was under $1/3$ in one case and complete in one case. The table 10 shows the result of different types of treatment after pre-operative traction.

In those cases where the result of traction could be controlled it had not changed the position of the epiphysis. As can be seen in Table 10 the results of treatment according to degree of slipping are approximately the same as in the rest of the series (Tables 10 and 17). This means that the traction had not much influenced the result of treatment.

After preoperative traction the epiphysis was fixed in seven cases according to Howarth, in five cases a simple nailing was performed and in two cases a wedge osteotomy was performed after which the capital epiphysis was fixed by Smith Petersen nail. In one case an arthroplasty was performed.

RESULTS

Assessment of results

Results were assessed by clinical examination of patients. Particular attention was paid to the patient's own estimation of the result, pains felt at rest or under strain, ability to work, and the patient's opinion in general. Secondly the degree of mobility of the hip was assessed by clinical examination and expressed according to Gade. Thirdly X-ray examination was carried out, with exposures taken in the antero-posterior and lateral or so-called Lauenstein positions in all cases.

Table 9

Assessment of Results

	Patient's estimation	Pain	Function	Movement index (Gade)	Radiographic appearance of hip
Excellent	Normal	None	Unrestricted	85 or over	Virtually normal hip, viable head good joint space
Good	Good hip, not quite normal	Does not interfere	Slightly restricted	75-85	Concruent surfaces viable head good joint space
Fair	Some trouble	Stops some activities	Definitely restricted	50-75	Some irregularity slipping of head narrowed joint space
Poor	In some cases trouble some	Partly disabling	Poor	Under 50	Joint space lost or necrosis of head

Table 11

Results of treatment after preoperative closed reduction

Degree of slipping	Results			
	No	Excellent or good	Fair	Poor
Slight	0	0	0	0
Under 1/3	1	0	1	0
Under 1/2	4	1	2	1
Over 1/2	5	1	2	2
Complete	0	0	0	0
All	10	2	5	3

As the table shows the results are no better than in the rest of the series and in some respects they are probably worse (Table 11 and 17)

The result at the time of follow up in those four cases in which the position was regarded as better after manipulation was good in one case fair in two cases and poor in one case. The distribution of results according to the degree of slipping is thus somewhat worse than in the rest of the material. As the number of cases of closed reductions is very small no accurate conclusions can be made but in this group there were more poor cases than in the whole material. The method of fixing the epiphysis after manipulation in the poor cases was nailing in one case (Fig 3) and Howarth operation in one case. The third case was manipulated first after which an open reduction was attempted and the head later replaced by the Judet prothesis. An arthrodesis was performed at another hospital later. In the first two cases a necrosis of the femoral head resulted with stiffening of the joint.

It seems therefore that the result of an attempted closed reduction is uncertain and contains a considerable risk of necrosis of the femoral head. If it is attempted it must preferably be done in a very recent slipping.

Conservative treatment

The group in which the treatment was considered as conservative because no operations were performed contained two cases considered as poor at follow up. In one of these an open reduction had been attempted at another hospital. The patient came for consultation a few years later when the epiphyseal plate had already closed the joint was stiff and no further operations

Table 10

Results in cases of preoperative traction

Under 1/3	4	3	1	0
Under 1/2	3	3	0	0
Over 1/2	7	5	0	2
Complete	1	0	1	0
All	16	12	2	2

The degree of slipping in the hips operated according to Howorth was over half of the extent of the epiphysis in five cases, under half in one case and under a third in one case. In one of these cases the result of treatment at the time of follow up was considered as poor, the other as excellent or good.

The degree of slipping in the cases in which a wedge osteotomy was performed was over half in one case and complete in one. Both cases were considered as good at the time of follow up. In those fixed by nailing the degree of slipping was slight in one case, under 1/3 in two and under 1/2 in two cases. They were all considered as good at the time of follow up. In two cases a closed reduction was attempted after a traction treatment at another hospital. The position of the head improved.

Closed reduction

In 4 cases in this series a closed reduction was attempted at another hospital. In six further cases a closed reduction was performed at our hospital. Only in four of these ten cases was the position of the capital epiphysis regarded as better by the surgeon after manipulation. These four cases were all recent slippings in which the closed reduction was attempted in a few days after accident; in two cases however a few weeks. Fig. 3 shows one case in which the position was regarded as better after a closed reduction but in which a necrosis of the head resulted.

Table 11 shows the results of different types of treatment after preoperative closed reduction.

Fig. 3. C. At this was a very recent case a closed reduction was performed and the epiphysis fixed by nailing. The position of the head is very good indeed. The nail is in a good position. D. A necrosis of the epiphysis developed in the middle of the epiphysis 8 months later and the nail had to be removed exactly a year after nailing. However the necrosis of the head was not used. E. Eight years after nailing the femoral head was quite irregular and the hip was stiff. A iliofemoral anastomosis was performed at another hospital and at the follow up ten years after nailing the angle of the right hip was 56° and 80° for the left hip which was also in flexion. The result in the right hip was regarded as poor because of the appearance in the X-ray. This was the only poor result among 51 nailings.

A

B

Fig 3 Right hip of a girl aged 12 at the time of nailing and closed reduction

A — The patient felt pain in the right hip and an X ray was taken at another hospital in both positions. No signs of a slip was seen and the patient was sent home. In the lateral X ray a slight slip is clearly visible.

B — The patient had fallen two days after the previous X ray was taken and the pain in the right hip became worse. In a new X ray a marked slip was seen and the patient was admitted to the hospital for nailing.

were indicated. The other was a neglected case in which the degree of slipping was more than half the extent of the epiphysis. This had not been diagnosed. On arrival at the hospital the epiphyseal plate had closed. The Gade mobility index was 12 in the first case and 46 in the other.

All	50	44	5	1

When a Smith Petersen or vitalium nail is used the literature records cases in which the nail pushes the capital epiphysis forward before the nail. It is also possible that a thick nail may split the epiphysis. In the present material complications of this type did not occur in a single case (Figs 4-6). In 3 cases however the nail was driven too far and penetrated the joint cartilage of the epiphysis. In only one case was necrosis of the epiphysis observed at follow up examination (Fig 3). A closed reduction had been performed in connection with nailing. In this case the caput had slipped about half the extent and closed reduction was performed during the operation. The patient felt no subjective discomfort worth mentioning. The Cade mobility index was 16 but because of changes in the X ray the condition as a whole was considered poor (Fig 3). In the 3 cases in which the nail had penetrated the joint cartilage no signs of this could be seen in the follow up X rays.

In 2 cases the nail came out and the patient had to be operated again. In one of these cases one month had elapsed since the operation and in the other case 5 months. In the latter the slipped epiphysis was bilateral and the nail came out on both sides. It therefore had to be driven in again several months later. In one case it was observed that the nail did not fix the epiphysis and the patient was re-operated 6 weeks after the first operation.

In only one case were Moore pins used. In this case a postoperative X ray control showed that these were placed in the dorsal part of the femoral neck where they did not fix the epiphysis. It was therefore necessary to remove them five weeks after operation. The condition healed nevertheless with a good result.

Table 12 shows the results at the time of follow up examination in cases in which no operations were performed

Table 12
Results of conservative treatment

Degree of slipping	Results			
	No	Excellent or good	Fair	Poor
<i>Slight</i>	1	1	0	0
<i>Under 1/3</i>	4	2	2	0
<i>Under 1/2</i>	1	0	1	0
<i>Over 1/2</i>	4	1	2	1
<i>Complete</i>	1	0	0	1
All	11	4	5	2

Three of these patients were treated elsewhere either by traction, immobilisation in plaster or immobilisation in bed. The result was excellent in one case, fair in two.

One patient was treated by immobilisation in plaster at our hospital. The result was fair. The others were allowed to move either with elbow crutches or with a Thomas Splint.

The conservative treatment was used in earlier years. The number of these cases is so small that no conclusions can be drawn. It looks as if the distribution of results was the same as in the rest of the material depending on the degree of slipping. As at least one of these patients had become worse and the degree of slip had increased during walking with elbow crutches it is obvious that fixing the epiphysis at an early stage diminishes the risk of further slipping and a poorer result. A conservative treatment seems therefore to be seldom justified.

OPERATIVE TREATMENT

Results by nailing

Table 13 shows the result of treatment according to degree of slipping in cases where the capital epiphysis was fixed by nailing.

Fig 5 Left hip, fractured II at the time of nail ing

A. The degree of slipping was considered to be less than half of the extent of the epiphysis. The lateral view on the right.

B. The epiphysis was fixed with a stainless steel nail without an attempt at closed reduction. (Closed reduction had been attempted at another hospital previously without success. Thus X-ray was taken 3 months after nail ing and as can be seen in the lateral view the protruding part of the neck of the upper corner has resorbed.

C. At the follow up 5 1/2 years after operation the hip movement were free except for the slight restriction of the internal rotation. No discomfort. No limp. Index of mobility according to C. I. was over 85. The result was considered excellent.

Fig 4 Left hip of a boy aged 14 at the time of nailing. This is the same case as in Fig 1.
A — The degree of hip joint dislocation was regarded as slight and the capital epiphysis fixed with a vitalium nail.
B — Two months after nailing.
C — Six years 3 months after operation at the follow up examination. The patient had done his military service. No pains in limb. No discrepancy of the legs. The Cade index over 85 in both hip. The result was regarded as excellent.

Howorth's operation

The Howorth operation or bone pegging has been practised at our hospital since 1961. Up to the end of 1963 a total of 13 operations according to this method had been performed. The number is now somewhat higher. The indication for this kind of fixing of the epiphysis has been a slipping of at least $\frac{1}{3}$ of the extent of the capital epiphysis usually more. The operation is in our opinion simple and easy to perform. The postoperative mobilisation of the patient is quick. The patients have been allowed to move with elbow crutches in 2-3 weeks after operation without weight bearing and full weight bearing is allowed according to signs of closure of the epiphyseal plate in the X ray. This has usually been in 2-3 months postoperatively. The passive and active joint movements are begun during the first postoperative week (Figs 7 and 8).

Table 14 shows the results of Howorth operation at the time of follow up examination according to the degree of slipping.

Table 14
Results with Howorth operation

Degree of slipping	Results			
	No	Excellent or good	Fair	Poor
Slight	0	0	0	0
Under $\frac{1}{3}$	2	2	0	0
Under $\frac{1}{2}$	5	2	2	1
Over $\frac{1}{2}$	8	7	0	1
Complete	0	0	0	0
All	15	11	2	2

In one case regarded as poor at the follow up a closed reduction had been attempted previously at another hospital without result. The degree of slip was under $\frac{1}{2}$ but was mostly backwards so that the position of the leg was in external rotation. Possibly a subtrochanteric correction osteotomy should have been indicated. This was not performed however. At the follow up almost 4 years after operation the movements of the hip were the same as before the operation except for rotations which were absent. The patient had no symptoms but in the X ray a slight arthrosis was evident. The Gade mobility index was 43.

 The slipping can be seen in the antero-posterior X ray too
B — The epiphys was fixed with a Smith Petersen nail The X ray was taken two months
 postoperatively
C — Nine years after operation No discomfort Plays tennis and other sports like skiing and
 swimming No limp No discrepancy of the legs Index of motion according to Code B The
 result was regarded as excellent

Fig. 8. The left hip of a girl aged 12 at the time of Howarth operation.
 A. The degree of slip was regarded as over half of the extent of the epiphysis. The internal rotation was absent before operation.
 B. Three months after Howarth operation. The bone pegs are clearly seen.
 C. Four years and seven months postoperation. No discomfort. Works in a shop as a salesgirl. No limp. No discrepancy. All movements are free including the internal rotation. Gade index 85. The result was regarded as excellent.

Fig 7 Left hip of a boy aged 13 at the time of Howarth operation

A - The degree of slip was regarded as less than third of the extent of the epiphysis. Adduction and internal rotation were limited before operation. The left leg was 1 cm shorter than the right.

B - 31 months after bone pegging operation according to Howarth.

C - 2 years and 5 months after operation at arthrodesis. No discomfort. The internal rotation limited. Walks without limp. The index of motion 77.5. The result was regarded as good.

Table 15
Results with wedge osteotomy

Degree of slipping	Results			
	No	Excellent or good	Fair	Poor
Slight	0	0	0	0
Under 1/3	0	0	0	0
Under 1/2	2	2	0	0
Over 1/2	6	6	0	0
Complete	1	0	1	0
Total	9	8	1	0

All these osteotomies were performed between 1957–1960. As reports by different authors were less encouraging they have not been performed since. As can be seen in Table 15 the results at the follow up in this small group of wedge osteotomies are surprisingly good and correspond to results reported recently by Dunn (1964) and others (Figs 9, 10 and 11). It is unlikely however that an osteotomy of the neck should be indicated in cases where the degree of slipping is small as the results without such an osteotomy in these cases are excellent or good even in this material.

Open reduction

Open reduction here means an operative repositioning of the epiphysis of the femoral head without resection of the neck.

The open reductions were performed in 1954–1963 and there were four in all.

After open reduction the femoral head was fixed with McLaughlin nail in two cases, with Smith Petersen nail in one case and was left without internal fixation in one case. Plaster immobilisation was used in two cases.

One case was regarded as excellent at follow up 11 years after operation. The Gade mobility index in this case was over 80. The patient had been classified as a Grade 1 during the military service. He had no symptoms, no limp, no discrepancy. The radiologic appearance of the head was good.

The result in two cases was regarded as good. The Gade mobility index was 81 in one patient and 75 in the other. They had no symptoms. One of them came to follow up 13 years after operation, the other 6 years after operation. Despite the lack of symptoms they were not accepted for military service. The head was slightly deformed in both cases in the X-ray (Fig. 12).

In the other case regarded as poor there was nothing exceptional. The degree of slip was over $1/2$. The patient was 4 weeks in bed postoperatively and began full weight bearing in 4 months. Later a subtrochanteric osteotomy was regarded as indicated for varus external rotation deformity, but for some reason this was not performed. Obviously this would not have improved the mobility, which poor was very already preoperatively. There were only 30 degrees of flexion while other movements were absent. At the follow up only 15 degrees of flexion were observed. The Gade mobility index was 9. The patient had no symptoms. In the X ray of the hip there was a superficial necrosis of the femoral head and acetabulum similar to the so called Waldenström's disease. In both cases regarded as poor no obvious reason for this was observed at the operation itself.

In one case regarded as fair at the follow up an attempt of closed reduction was made during the operation. The position of the head could not be changed however. In a postoperative X ray one tibial graft was observed to have penetrated the surface of the femoral head into the joint. At the follow up 5 years after operation the femoral head was deformed in the X ray but the tibial grafts had resorbed.

In both cases regarded as fair a subtrochanteric osteotomy was performed. The Gade mobility index was 61 in one case and 66 in the other. The latter was a patient with a pituitary tumour. His height at the follow up was 218 cm. He was treated by radiotherapy before orthopedic operations.

As our indications for Howarth operation have occurred in patients with more advanced slippings the results can be regarded as good in our opinion (Figs 7, 8).

Wedge osteotomy

In nine cases in this material a wedge osteotomy of the femoral neck was performed. The wedge was taken from the middle of the neck with its base in the upper anterior part so that the varus external rotation deformity could be corrected. In five cases a postoperative immobilisation in a plaster hip spica for from 6 to 8 weeks was used. The fragments were fixed in all cases with a Smith Petersen nail. In one case the nail came out of the neck after 4 weeks and the patient had to be operated again. An intertrochanteric correction osteotomy was done at the same time as refixation of the fragments. The result in this case was excellent six years later at the follow up.

The results at the follow up according to the degree of slipping are shown in Table 15.

Table 15
Results with wedge osteotomy

Degree of slipping	Results			
	No	Excellent or good	Fair	Poor
Slight	0	0	0	0
Under 1/3	0	0	0	0
Under 1/2	2	2	0	0
Over 1/2	6	6	0	0
Complete	1	0	1	0
Total	9	8	1	0

All these osteotomies were performed between 1957–1960. As reports by different authors were less encouraging they have not been performed since. As can be seen in Table 15 the results at the follow up in this small group of wedge osteotomies are surprisingly good and correspond to results reported recently by Dunn (1964) and others (Figs 9, 10 and 11). It is unlikely however that an osteotomy of the neck should be indicated in cases where the degree of slipping is small as the results without such an osteotomy in these cases are excellent or good even in this material.

Open reduction

Open reduction here means an operative repositioning of the epiphysis of the femoral head without resection of the neck.

The open reductions were performed in 1954–1963 and they were four in all. After open reduction the femoral head was fixed with McLaughlin nail in two cases, with Smith Petersen nail in one case and was left without internal fixation in one case. Plaster immobilisation was used in two cases.

One case was regarded as excellent at follow up 11 years after operation. The Gade mobility index in this case was over 80. The patient had been classified as a Grade A during the military service. He had no symptoms, no limp, no discrepancy. The radiologic appearance of the head was good.

The result in two cases was regarded as good. The Gade mobility index was 81 in one patient and 75 in the other. They had no symptoms. One of them came to follow up 13 years after operation, the other 6 years after operation. Despite the lack of symptoms they were not accepted for military service. The head was slightly deformed in both cases in the X ray (Fig. 12).

In the other case regarded as poor there was nothing exceptional. The degree of slip was over $1/2$. The patient was 4 weeks in bed postoperatively and began full weight bearing in 4 months. Later a subtrochanteric osteotomy was regarded as indicated for varus external rotation deformity, but for some reason this was not performed. Obviously this would not have improved the mobility, which poor was very already preoperatively. There were only 30 degrees of flexion while other movements were absent. At the follow up only 15 degrees of flexion were observed. The Gade mobility index was 9. The patient had no symptoms. In the X ray of the hip there was a superficial necrosis of the femoral head and acetabulum similar to the so called Waldenström's disease. In both cases regarded as poor no obvious reason for this was observed at the operation itself.

In one case regarded as fair at the follow up an attempt of closed reduction was made during the operation. The position of the head could not be changed however. In a postoperative X ray one tibial graft was observed to have penetrated the surface of the femoral head into the joint. At the follow up 5 years after operation the femoral head was deformed in the X ray but the tibial grafts had resorbed.

In both cases regarded as fair a subtrochanteric osteotomy was performed. The Gade mobility index was 61 in one case and 66 in the other. The latter was a patient with a pituitary tumour. His height at the follow up was 218 cm. He was treated by radiotherapy before orthopedic operations.

As our indications for Howarth operation have occurred in patients with more advanced slippings the results can be regarded as good in our opinion (Figs 7, 8).

Wedge osteotomy

In nine cases in this material a wedge osteotomy of the femoral neck was performed. The wedge was taken from the middle of the neck with its base in the upper anterior part so that the varus external rotation deformity could be corrected. In five cases a postoperative immobilisation in a plaster hip spica for from 6 to 8 weeks was used. The fragments were fixed in all cases with a Smith Petersen nail. In one case the nail came out of the neck after 4 weeks and the patient had to be operated again. An intertrochanteric correction osteotomy was done at the same time as refixation of the fragments. The result in this case was excellent 15 years later at the follow up.

The results at the follow up according to the degree of slipping are shown in Table 15.

Fig 10 The left hip of a girl aged 14 at the time of a wedge osteotomy

- A. The degree of L.P. was estimated as over half of the extent of the epiphysis. Rotations and alignment were absent before operation. The left extremity was $2\frac{1}{2}$ cm shorter.
- B. A few weeks after a wedge osteotomy and fixation with a 5mm Petersen nail.
- C. Eighteen months after operation. Walks almost without a limp. The left leg is $1\frac{1}{2}$ cm shorter. The internal rotation is limited, otherwise hip movements are free. No discomfort. Index of mobility 85. The result was regarded as excellent.

Fig 9 The left hip of a boy aged 14 at the time of a wedge osteotomy
A — The degree of slip was regarded as over half of the extent of the epiphysis. The boy felt pain in the hip for 6 months
B — One month after a wedge osteotomy. The fragments were fixed with a Smith Petersen nail and a plaster hip spica was applied for a month
C — Nine years 6 months postoperatively. No discomfort. Slight limp. The left leg is 2 cm shorter. Except for internal rotation the hip movements are free. Index of mobility 77. Result was considered good.

The result in one case was regarded as poor at the follow up. In this case the fragments were fixed with a McLaughlin nail which obviously penetrated the surface of the femoral head into the joint. This was evident in the special control X rays after operation. The nail was left in place however and resulted in cartilage necrosis of the femoral head. At the follow up 4 years after operation the patient felt pains on strain. The Gade mobility index was 54 but because of the appearance in the X ray the result was regarded as poor (Fig. 13).

Thus the results in three of four cases were excellent or good after 6–13 years follow up. Only one result was regarded as poor and even in this case the reason for a poor result was not the open reduction itself but a nail penetrating the joint cartilage. The number of operations is so small however that no further conclusions can be made according to the value of this operation or the risk involved.

ALL TYPES OF TREATMENT

The result with all types of treatment summarised are shown in Table 16.

Table 16
Results with different types of treatment

All	98	71	20	7

The group other operations contains 7 subtrochanteric and intertrochanteric osteotomies, one drilling operation and the previously mentioned Judet arthroplasty after an unsuccessful open reduction. In the present material 5 other intertrochanteric or subtrochanteric osteotomies were performed after nailing or Howorth operation. These have not been mentioned separately however. The Judet arthroplasty led to a poor result. It was performed as mentioned in connection with an unsuccessful attempt at open reduction and the arthroplasty itself produced a painful condition later.

Fig 11 Right hip of a girl aged 11 at the time of a wedge osteotomy
A - The degree of slip was complete. Traction was applied for one month without effect
B - One week after a wedge osteotomy and fixation with a vitallium nail. A slight necrosis of the epiphysis was noticed at the site of the operation and a Thomas splint was used. The nail was removed two years later.
C - Seven years after operation. No discomfort. Walks with a slight limp. No discrepancy of the legs. The femoral heads are restricted. Gade index 10. The result was regarded as fair.

The result in one case was regarded as poor at the follow up. In this case the fragments were fixed with a McLaughlin nail which obviously penetrated the surface of the femoral head into the joint. This was evident in the special control X rays after operation. The nail was left in place however and resulted in cartilage necrosis of the femoral head. At the follow up 4 years after operation the patient felt pains on strain. The Gade mobility index was 54 but because of the appearance in the X ray the result was regarded as poor (Fig. 13).

Thus the results in three of four cases were excellent or good after 6–13 years follow up. Only one result was regarded as poor and even in this case the reason for a poor result was not the open reduction itself but a nail penetrating the joint cartilage. The number of operations is so small however that no further conclusions can be made according to the value of this operation or the risk involved.

DISCUSSION

The etiology of the slipped upper femoral epiphysis is quite evidently connected with hormonal influence at least in some respect. Roughly 30 per cent of the patients in this material were overweight or even more clearly had an endocrine disturbance. As Harris (1950) observed an excess of the growth hormone may weaken the epiphyseal plate and the sex hormone strengthens it against tangential strain. The tallest boy in this material was 216 cm or 7 ft 3 ins. It is naturally of some importance that not all cases of slipped epiphysis are bilateral. On the other hand the diagnosis of very slight slip which may recover without treatment is very difficult. Using a careful and thorough technique of examination Billing and Severin (1959) found evidence of a bilateral slip in 80 per cent of cases. A mere weakening of the epiphyseal plate without displacement may even then escape diagnosis (Figs 1-2). Thus a very high percentage of cases are after all bilateral.

If a lateral radiograph is taken the diagnosis of a slipped femoral epiphysis is in most cases easy. This is often neglected however and in an anteroposterior radiograph a slight slip can only be diagnosed with difficulty despite the typical signs described by Jerre (1950) and Waldenström (1939).

Howorth (1966) has stated that there exists a so-called *preslipping stage* in which there is only swelling of the synovial membrane and villous formation. In this material there were 11 hips in which the *only sign* of a slip was widening or irregularity of the epiphyseal line in the lateral X-ray or a slip of 1-2 mm only. Six of these patients felt pains in the hip but five did not. Thus obviously a *preslipping stage* may exist without symptoms.

Traction did not seem to affect the *result of treatment* in this material. Its use has therefore been abandoned at our hospital in the preoperative treatment of a slipped epiphysis.

Closed reduction was successful in *four cases out of ten* in this material. Of these four cases in which the closed reduction was considered to have improved the position of the head only one was regarded as good at the follow-up. One was poor and two fair. It seems to us that a closed reduction

Denervation was carried out later, but brought no relief. Eventually arthrodesis was performed at another hospital. The result was naturally considered poor. In the two conservative cases with poor results, the patient on whom operative reduction had been attempted elsewhere came for follow up examination 6 years after the original operation without the slightest discomfort. There was a 5 cm shortening of the lower limb, the Gade mobility index was 12, and the X ray picture showed that the capital epiphysis had almost disappeared. The other patient came for follow up 9 years after the original visit. There had been a slipping of over half the extent of the epiphysis. He had advanced stiffness in the hip. The X ray showed that the head was completely deformed. The Gade index was 46. The result was considered poor.

As shown earlier in the literature the extent of slipping has an important effect on results. Table 17 therefore shows the whole material classified according to degree of slipping, irrespective of treatment.

Table 17

Result with all types of treatment according to displacement

Degree of slipping	No Hips	Results		
		Excellent or good	Fair	Poor
Slight	18	18	—	—
Under 1/3	25	20	5	—
Under 1/2	24	16	7	1
Over 1/2	29	17	7	5
Complete	2	—	1	1
All	98	71	20	7

Although operations in this series have been performed by several different methods and by different surgeons over a period of 20 years and although some cases have remained untreated because of neglect or incorrect diagnosis or have been treated conservatively it appears that the extent of slipping has a vital influence on results. Thus in cases which have been considered satisfactory or poor at follow up slipping has usually been half or more than half the extent of the capital epiphysis. This is natural because deformity resulting from considerable slipping and disturbance in development of the femoral head obviously has an adverse effect on the result regardless of treatment.

DISCUSSION

The etiology of the slipped upper femoral epiphysis is quite evidently connected with hormonal influence at least in some respect. Roughly 30 per cent of the patients in this material were overweight or even more clearly had an endocrine disturbance. As Harris (1950) observed an excess of the growth hormone may weaken the epiphyseal plate and the sex hormone strengthens it against tangential strain. The tallest boy in this material was 218 cm or 7 ft 3 ins. It is naturally of some importance that not all cases of slipped epiphysis are bilateral. On the other hand the diagnosis of very slight slip which may recover without treatment is very difficult. Using a careful and thorough technique of examination Billing and Severin (1959) found evidence of a bilateral slip in 80 per cent of cases. A mere weakening of the epiphyseal plate without displacement may even then escape diagnosis (Figs 1-2). Thus a very high percentage of cases are after all bilateral.

If a lateral radiograph is taken the diagnosis of a slipped femoral epiphysis is in most cases easy. This is often neglected however and in an anteroposterior radiograph a slight slip can only be diagnosed with difficulty despite the typical signs described by Jerre (1950) and Waldenström (1939).

Howorth (1966) has stated that there exists a so-called *preslipping stage* in which there is only swelling of the synovial membrane and villous formation. In this material there were 11 hips in which the only sign of a slip was widening or irregularity of the epiphyseal line in the lateral X-ray or a slip of 1-2 mm only. Six of these patients felt pains in the hip but five did not. Thus obviously a preslipping stage may exist without symptoms.

Fraction did not seem to affect the result of treatment in this material. Its use has therefore been abandoned at our hospital in the preoperative treatment of a slipped epiphysis.

Closed reduction was successful in four cases out of ten in this material. Of these four cases in which the closed reduction was considered to have improved the position of the head only one was regarded as good at the follow-up. One was poor and two fair. It seems to us that a closed reduction

Denervation was carried out later, but brought no relief. Eventually arthrodesis was performed at another hospital. The result was naturally considered poor. In the two conservative cases with poor results, the patient on whom operative reduction had been attempted elsewhere came for follow up examination 6 years after the original operation without the slightest discomfort. There was a 5 cm shortening of the lower limb, the Gade mobility index was 12, and the X ray picture showed that the capital epiphysis had almost disappeared. The other patient came for follow up 9 years after the original visit. There had been a slipping of over half the extent of the epiphysis. He had advanced stiffness in the hip. The X ray showed that the head was completely deformed. The Gade index was 46. The result was considered poor.

As shown earlier in the literature, the extent of slipping has an important effect on results. Table 17 therefore shows the whole material classified according to degree of slipping, irrespective of treatment.

Table 17

Result with all types of treatment according to displacement

Degree of slipping	No Hips	Results		
		Excellent or good	Fair	Poor

Under 1/2	24	16	7	1
Over 1/2	29	17	7	5
Complete	2	—	1	1
All	98	71	20	7

Although operations in this series have been performed by several different methods and by different surgeons over a period of 20 years and although some cases have remained untreated because of neglect or incorrect diagnosis or have been treated conservatively, it appears that the extent of slipping has a vital influence on results. Thus in cases which have been considered satisfactory or poor at follow up slipping has usually been half or more than half the extent of the capital epiphysis. This is natural because deformity resulting from considerable slipping and disturbance in development of the femoral head obviously has an adverse effect on the result regardless of treatment.

SUMMARY

The authors have analysed a total of 99 treated hips with a slipped femoral epiphysis of which 98 were re-examined at follow up. The average observation time was 6.7 years. The longest observation time was 19 years. There were 19 bilateral cases. The degree of slipping was assessed from a lateral X-ray. Slipping was classified as slight under 1/3, under 1/2, over 1/2 and complete slipping.

Fifty-one hips were treated by nailing and 50 of these patients appeared for follow up. Fifteen hips were treated by Howorth's bone pegging operation, 9 by wedge osteotomy, 4 by open reduction, 7 by intertrochanteric or subtrochanteric osteotomy. One was treated by Judet arthroplasty and one by drilling. Eleven cases were treated conservatively, i.e. no operation was performed. Actual conservative treatment was given to 4 patients only. The remainder had been operated on in other hospitals or neglected.

Results were assessed from the patient's own estimation, from clinical examination and from X-rays. In clinical examination the Gade index was used. An index of 50 or less was considered poor.

At follow up examination of the 50 nailed cases 44 were excellent or good, 5 fair and only one was poor. Of those 15 operated by the Howorth method 11 were excellent or good, 2 fair and 2 poor. After wedge osteotomy, 8 cases were good or excellent, one was fair and none poor. After open reduction 3 were excellent or good, one was poor. The present material showed that the extent of the slipping had a marked effect on the result of treatment. When the slipping was less than half the extent of the epiphysis, excellent or good results were achieved in 54 cases of 67 (80.6 per cent), fair in 12 (17.9 per cent) and poor in only one (1.5 per cent) regardless of the type of treatment or the method of operation. When the slipping was over half, however, 17 cases out of 31 (54.8 per cent) were excellent or good, 8 fair (25.8 per cent) and 6 poor (19.4 per cent). In the whole material 71 cases out of 98 (72.5 per cent) were excellent or good, 20 fair (20.4 per cent) and 7 poor (7.1 per cent).

is only indicated, if the slip is very recent and the degree of slipping is at least half the extent of the capital epiphysis, since results by nailing or Howorth operation without reduction are reasonably good in mild cases. On the other hand, if the slipping is severe or complete the position of the head should be corrected either by closed reduction or better still with a wedge osteotomy.

The number of cases of open reductions and wedge osteotomies is very small so that absolute conclusions cannot be drawn from the results obtained. It seems, however, as if a wedge osteotomy might have a place in the treatment of a severe slip if the operation can be performed by a skilled surgeon.

The Howorth operation was regarded as an easy and safe procedure. The result in two cases regarded as poor at the follow up may result from other causes than the operation method itself, probably too wide an exposure at operation. In most cases operated according to Howorth the degree of slipping was more than half the extent of the capital epiphysis, and this of course affects the result.

The results by nailing with a Smith Petersen nail in this series are mostly good. Complications that might occur with a trifin nail were observed only in very few cases and recovered without treatment in most of them. Only one case in 50 was regarded as poor at the follow up, and in this case a closed reduction had also been performed. In recent years we have used only thin nails intended for children. The only complication that occurred was that the nail reached too far and penetrated the joint cartilage. This of course can be prevented with proper operation technique and with a careful X ray control.

Follow up examination showed that the fixation of the epiphysis is indicated in cases of slight and moderate slipping because its neglect may allow an increase of slipping later and affect the result adversely. In the entire material the results were much better with any type of treatment in cases of slight or moderate slip. The more severe the slip the less favorable is the result. Therefore an early diagnosis of a slipped upper femoral epiphysis is the surest guarantee of a good result, as it is in the treatment of many other conditions in medical practice.

Preface

Achilles heel — the athlete's vulnerable spot — gave the impulse to this investigation

Curt Franksson inspired, criticized and set the pace from start to finish

Lennart Widen encouraged me and provided facilities for the neurophysiological examinations

Anders Persson carried out the electromyographic examinations and analysed these and the operative findings

Erik Lindgren interpreted the X-ray findings

Hans Nordenstam analysed the histological material

Torgny Sjöstrand encouraged and supported the work

Stefan Jacobson's, Elin Kopman's and Bertil Wallerman's photographic skill lent colour and shape to the work

Lars Glasser's old Dalecarlian country house provided an inspiring and peaceful working place

The investigation was supported financially by Folksam Insurance Company and the Poliklinikkommittén of the Swedish Sports Federation

Thus it was possible to carry out the work reported in the following

Introduction

Subcutaneous partial rupture of the Achilles tendon has been regarded as an uncommon injury (see the following) In a short period of time however the author has diagnosed this condition relatively often The object of this investigation was to throw light on the nature of the injury and to present a new method (by electromyography) for diagnosing the condition

Introduction

Subcutaneous partial rupture of the Achilles tendon has been regarded as an uncommon injury (see the following) In a short period of time however the author has diagnosed this condition relatively often The object of this investigation was to throw light on the nature of the injury and to present a new method (by electromyography) for diagnosing the condition

Definition

Subcutaneous partial rupture of the Achilles tendon refers here to a tear involving a varying number of fibres in the free portion of the Achilles tendon, usually leaving most fibres intact. To distinguish clinically a partial rupture from a complete rupture is not difficult, because plantar flexion of the foot does not occur on Thompson's test (1960) — manual compression of the triceps surae belly — if the rupture is complete. Absence of this reflex is pathognomonic for complete rupture of the Achilles tendon.

The Achilles tendon is formed by the fusion of fibres from the medial and lateral bellies of the gastrocnemius and the soleus. The partial rupture of the tendon can involve a greater or smaller section of

- 1) the medial portion of the tendon
- 2) the lateral portion of the tendon
- 3) the central or the soleus portion of the tendon
- 4) all three portions of the tendon as in some central ruptures but most of the tendon fibres remaining intact

Histologically the partial rupture is characterized by devitalized tendon tissue with frayed fibrous structure and around these areas granulation tissue which, according to the age of the rupture is transformed into more or less tendon like connective tissue.

History

Complete subcutaneous rupture of the Achilles tendon was first described by Pare in 1575 and has since been described by several authors for instance Petit in 1724 af Acrel in 1759 and Arner & Lindholm in 1909 The last named authors presented a study of 92 patients operated on for subcutaneous Achilles tendon rupture which was complete in all the cases They hold that isolated partial rupture of the free portion of the Achilles tendon does not occur or is at least extremely rare

Arner & Lindholm (1909) state that of all the published cases of so called partial rupture which were explored operatively only one (Kolb & Salem 1953) could from the functional standpoint possibly be regarded as partial On the basis of his observations in a series of 240 cases from the Bohler Clinic in Vienna all being cases of complete Achilles tendon rupture Schonbauer (1955 1966) questions the existence of the partial rupture

Kolb & Salem (1953) report 2 cases of Achilles tendon rupture treated by operation in one case the rupture involved half the tendon The rupture may possibly be judged as partial in the other case as well According to Kolb & Salem the reason why only a small number of partial ruptures have been described would be that because of the clinical methods of examination a difference between "strain — zerrung — and partial rupture of the tendon cannot be definitely established They also state that it is difficult to diagnose a partial rupture clinically Ignorance of this injury however can lead to deterioration or complete rupture as a result of unsuitable treatment (forced exercise massage)

Wedel (1904) and van de Kamp (1904) each described a case of partial Achilles tendon rupture In Wedel's case there was a medial intact tendon running the thickness of a wool thread 2 mm in thickness Schonbauer (1955) believes that both cases were misinterpreted and that in both of them the intact portion of the tendon consisted of the plantaris tendon which according to Alker (1907) can descend medial as well as in front of behind and lateral to the Achilles tendon

In 1960 Solheim reported a series of 76 cases of complete and 1 case of partial rupture the latter was initially treated conservatively for 5 months

Definition

Subcutaneous partial rupture of the Achilles tendon refers here to a tear involving a varying number of fibres in the free portion of the Achilles tendon usually leaving most fibres intact. To distinguish clinically a partial rupture from a complete rupture is not difficult, because plantar flexion of the foot does not occur on Thompson's test (1960) — manual compression of the triceps-surae belly — if the rupture is complete. Absence of this reflex is pathognomonic for complete rupture of the Achilles tendon.

The Achilles tendon is formed by the fusion of fibres from the medial and lateral bellies of the gastrocnemius and the soleus. The partial rupture of the tendon can involve a greater or smaller section of

- 1) the medial portion of the tendon
- 2) the lateral portion of the tendon
- 3) the central or the soleus portion of the tendon
- 4) all three portions of the tendon, as in some central ruptures but most of the tendon fibres remaining intact

Histologically, the partial rupture is characterized by devitalized tendon tissue with frayed fibrous structure and around these areas granulation tissue, which, according to the age of the rupture, is transformed into more or less tendon like connective tissue.

Present series

The series comprises 24 patients who over the 4 year period 1964—1967 were examined for Achilles tendon injuries at the Department of Surgery and the Physiotherapy Department at Serafimerlasarettet in Stockholm (Tables I—III) and who had undergone operation for the injury at least 1 year previously (see below) * It will be seen from Tables II and III that all the patients excluding one (no 3) engaged in some form of sport The explanation of this is that the author is physician to the Swedish Amateur Athletic Association and to football and ice hockey teams of top class players In this capacity I came into direct contact with 13 patients The other 11 were referred to me because of my interest in sports injuries 6 patients were referred from hospital physicians or private practitioners in the Stockholm area and 5 from hospital physicians outside the Stockholm area Nine cases were by the referring physician diagnosed as achillotendinitis and 2 as rupture of the gastrocnemius muscle

The distribution by sex and age is shown in Table I It will be seen that there is only one woman (case 9) The patients can be divided into a lower age group of 19—29 years including champion athletes alone (Table II)

TABLE I
Age and sex distribution

40—49	8	0	8
50—59	1	1	
60—65		0	2
Total	3	1	24

I have operated upon a further 13 patients but as the observation period in these cases less than 1 year they are not included here

without any effect. Operation revealed a rupture of half the tendon with calcium deposits. In 1964 Lanz described a case of partial spontaneous transverse rupture of the Achilles tendon, 2 cm above the insertion in a 62-year old woman. He also discussed the question whether or not the Achilles tendon always ruptures completely. In Lanz's opinion the diagnoses in the published cases of partial rupture treated conservatively can not be regarded as confident and he considers that the sporadic cases treated operatively and published as partial ruptures must be viewed very critically. According to Baerzner (1957), individual bundles of tendon fibres can rupture at different levels and thus simulate partial ruptures. Lanz considers that exposure of the whole tendon is necessary in order to prove that a true partial rupture has occurred.

Present series

The series comprises 24 patients who over the 4 year period 1964—1967 were examined for Achilles tendon injuries at the Department of Surgery and the Physiotherapy Department at Serafimerlasarettet in Stockholm (Tables I—III) and who had undergone operation for the injury at least 1 year previously (see below) * It will be seen from Tables II and III that all the patients excluding one (no 3) engaged in some form of sport. The explanation of this is that the author is physician to the Swedish Amateur Athletic Association and to football and ice hockey teams of top class players. In this capacity I came into direct contact with 13 patients. The other 11 were referred to me because of my interest in sports injuries. 6 patients were referred from hospital physicians or private practitioners in the Stockholm area and 5 from hospital physicians outside the Stockholm area. Nine cases were by the referring physician diagnosed as achillotendinitis and 2 as rupture of the gastrocnemius muscle.

The distribution by sex and age is shown in Table I. It will be seen that there is only one woman (case 9). The patients can be divided into a lower age group of 19—29 years including champion athletes alone (Table II)

Champion athletes

Case no	Age yr	Occupation and branch of sport	Causal violence	Interval between rupture and operation
1	24	Engineer medium distance runner	Spurt in a 3000 metre race	6 months
2	25	Policeman skier	Excessive weight bearing on foot in grappling with a drunkard	1 month
4	29	Engineer ice hockey player	Pulled up suddenly at ice hockey	7 weeks
6	29	Electrician footballer	Tripped over at work	8 months
14	24	University student long distance runner	Barefoot running	6 months
15	22	Buyer hurdler	Slipping	4 months
18	27	Farmer long distance runner	Spurt in a 10 000 metre race	5 day
19	8	Engineer cross country runner	Tripped over tree root	12 months
22	22	Student of technology sprinter	Violent push off at a 100 metre race	3 months
23	23	Gymnastics master medium distance runner	Training pressure of shoe stiffener	6 months
24	19	Office clerk medium distance runner	800 metre race on wooden floor	8 months

and a higher age group of 38—65 years comprising various kinds of athletes (Table III). The latter group includes the only patient who was not an athlete (case 3) but who was physically very active.

The following intervals had elapsed between operation and examination

- 1 year — 11 cases
- 2 years — 10 cases
- 3 years — 3 cases

* In the following the term athlete will refer to a person who performs strenuous physical exercise 2—3 times a week.

Subcutaneous rupture of the Achilles tendon has been attributed to pathological processes in the tendon tissue and/or trauma. Rupture of a pathologically changed tendon can result from insult which is so slight that the patient himself does not notice it - so called spontaneous rupture (Christensen 1954). Several authors from Friauf (1891) to Boyd (1945) have described numerous factors that lower the strength of the tendon such as syphilis gonorrhoea tuberculosis uratic arthritis and pyogenic infections. Other causes are tendinitis suggested by Malbec (1935) and Silfverstöld (1941) and tumours and cysts by Christensen. Repeated minor trauma particularly in certain occupations would also lead to rupture of the small vessels with accompanying impaired circulation which could predispose to later ruptures (Albrecht 1925 Bate 1951 Wachs 1951 Borsey 1952). Oral steroid treatment (Lee 1961 Gjone 1962 Melmed 1965 and others) and local steroid injections in connection with trauma (Lee 1957) have also been discussed as aetiological factor.

Of the above listed causal factors steroid injections and trauma played a part in the present series of cases.

Steroid injections

Since Hollander (1951) published his work on the beneficial anti-inflammatory effect of locally injected hydrocortisone in bursitis and tendinitis this treatment has been widely used in achilles tendinitis, not least in sports injuries. Wrenn Goldner & Markes (1954) in an experimental study on dogs report on the effect of cortisone on the healing process and the tensile strength of the tendon after severing of the tendon and subsequent suturing. They found that daily intramuscular administration of 10 mg of cortisone per kg body weight for 3 weeks prevented excessive formation of peritendinous fibrous tissue but it did not prevent end to end healing of the tendons. On weight bearing exercise it was found that the strength in the sutured area of the tendon was consistently lower than in the control cases. Although the tendon treated with cortisone for 3

Occupation and form of athletics will be seen from Tables II and III. A striking fact is that heavy manual labour is represented by only 2 cases (farmer and carpenter) as against white-collar and similar occupations by 22 cases.

The branches of athletics are mostly of the track-and field type, cross country running, orienteering and skiing, all of which call for greater fitness and require more intense and lengthy running practice with resulting greater strain on the Achilles tendon. Team sports (football, ice hockey, handball) are represented by only 3 cases.

In view of the fact that diminished perfusion with impaired oxygen supply to the tendon tissue has been discussed as a causative factor in devitalization of the Achilles tendon (Wuscheck, Kempe & Arent 1966), the haemoglobin values were studied and the following results were obtained.

Hb =	11.9 g per 100 ml	2 cases
	12.7—13.9 g per 100 ml	6 cases
	14.0—15.0 g per 100 ml	15 cases
	16.7 g per 100 ml	1 case

It will be seen that the haemoglobin value was below the lower limit of normal range — 12.0 g per 100 ml — in 2 cases (nos 17 and 18).

TABLE IV

Corticosteroid treatment in partial ruptures of Achilles tendon

24	Tendinitis	0	—	1	10 days

a suggestion of dystrophic calcification. The appearance of parts of the areas resembled that of thopus.

It will be seen from the above account that just over half the patients had not received steroid injections before the rupture. In the rest the time-relationships among other factors argue against the possibility that the steroid injections would have been of direct aetiological significance. They might have played a part by relieving the patient of the symptoms attending a small rupture or some other injury of the Achilles tendon and so allowed increased weight bearing on the tendon thus being concerned in causing the clinically manifest rupture.

weeks, was 40 % weaker than in the controls, the healing in both the cortisone and the control group was adequate for normal tendon function

Asboe-Hansen (1956) and Zachariae (1966), in studies of the local effect of corticosteroids, emphasize that these drugs inhibit new formation of connective tissue and produce an anti inflammatory effect, but may cause increased degeneration and necrosis of the tissues

Only in 3—4 of the published cases of partial subcutaneous rupture of the Achilles tendon can the diagnosis probably be regarded as confident. As my material from the Department of Surgery at Serafimerlasarettet over the period 1964—1966 includes 24 cases of partial rupture the question arises whether these could be complications of local steroid treatment of achillotendinitis, this treatment being relatively widely used during this period of time. The series has therefore been analysed with respect to the number of local steroid injections before and after the occurrence of suspected rupture and the interval of time between injection and rupture (Table IV)

It will be seen from Table IV that intra- or peritendinous corticosteroid injection had been given

Before rupture	6 cases
Before and after rupture	4 „
After rupture	8 „
Neither before nor after rupture	6 „

Accordingly, 14 patients had not received any steroid injection before the rupture. Out of the 10 patients who had been given local steroid injection before the rupture 2 (nos 5 and 6) had received one injection about 1 year before the rupture and had had no trouble from the Achilles tendon during this period of time, in spite of intense activity. It is therefore hard to believe that the injection in these cases could have been of any aetiological significance. In Cases 2, 4, 10, 19, 21 and 23 the injection which caused relief of symptoms was given 2—4 months before the partial rupture. In at least 4 of these cases the local symptoms present at the time of the injection were in a part of the tendon other than the site of rupture. Patients nos 11 and 23 received one steroid injection 5 and 6 weeks, respectively, before the injury and were free from symptoms until they sustained the rupture.

Histological examination of the surgical cases showed no difference in the picture between the steroid treated and the non steroid treated patients with the possible exception of Case 22 in which the devitalized tendon tissue was found to contain a few small defined necrotic areas with

TABLE IV

Corticosteroid treatment in partial ruptures of Achilles tendon

Case no	Diagnosis	Before rupture		After rupture

a suggestion of dystrophic calcification. The appearance of parts of the areas resembled that of thopus.

It will be seen from the above account that just over half the patients had not received steroid injections before the rupture. In the rest the time-relationships among other factors argue against the possibility that the steroid injections would have been of direct aetiological significance. They might have played a part by relieving the patient of the symptoms attending a small rupture or some other injury of the Achilles tendon and so allowed increased weight bearing on the tendon thus being concerned in causing the clinically manifest rupture.

Trauma

The Achilles tendon can be ruptured by direct or indirect violence. It is believed that rupture can occur when the violence is applied at right angles to a tense tendon (Kolb & Salem). Indirect violence is considered to be the more common cause. Arner & Lindholm, in analysing the causes of complete rupture distinguished between three main types of indirect violence.

1) Pushing off with the weight-bearing forefoot flexed in a plantar direction while extending the knee joint, for instance at the start of a sprint, in running and in some types of jumps. In this coordinated movement the calf muscle is maximally contracted,

2) Sudden and unexpected violent dorsiflexion of the ankle when the foot is in an intermediate position for instance in slipping on a stair or stumbling into a hole the patient falls forward and the heel sinks down suddenly. In this type of violence the calf muscle is usually moderately contracted and becomes maximally contracted in the sudden reflected and uncontrolled movement.

3) Violent dorsiflexion of the foot flexed in a plantar direction, for instance on jumping or falling from a height. The calf muscle is strongly contracted and the sudden violence to the foot leads to marked stretching of muscle and tendon.

The Achilles tendon, being one of the strongest tendons of the body, takes a load of about 240 kg at ordinary walking and of about 600 kg at running. The load may amount to 900 kg at very swift running (Carlsoo 1968). Arner, Lindholm & Orell (1959) in their series of 74 cases of complete rupture examined histologically, noted degenerative changes in the tendon in all the cases, even in those of the patients operated on only a few hours after the injury (see also Davidsson 1956). They attributed the histological changes to impaired blood supply. Angiographic and microangiographic studies by Lägergren & Lindholm (1959) have shown that the most frequent site of rupture of the Achilles tendon is the segment least vascularized namely 2—3 cm above the insertion of the tendon. Arner & Lindholm give the following explanation of the Achilles tendon rupture. Training and increased activity of a muscle lead to hypertrophy and increased vascularisation of muscular tissue (Petren, Sjöstrand & Sylven 1936), and probably also of tendon tissue during an athlete's active years. If these are followed by inactivity degenerative changes will occur in the tendon tissue with resulting impaired tensile strength. Ricklin (1962) states that the elasticity diminishes rapidly after age 30 with progressing

cbliteration of the vessels of the tendon. Degeneration and fragmentation of the tendon fibres will reduce the tensile strength of the tendon.

Ricklin also maintains that in highly active athletes exhaustion is a factor that plays an important part in causing structural changes in the Achilles tendon with resulting greater tendency to rupture. A comparison is suitably made with the insufficiency fractures of the fibula which are largely on the same level as the Achilles tendon ruptures and which occur relatively often in champion athletes during periods of hard training. As regards the aetiology of these fractures they have been attributed for instance to a change in the submicroscopical bone crystals and dissolution of the tissue connecting them (Henschen 1936).

On the basis of Cummins (1949) observation that the tendon fibres from the gastrocnemius and the soleus converge as they descend while rotating toward the insertion on the calcaneus Christensen (1954) suggested that in running and jumping there occurs a saw like friction between the tendon fibres especially in persons in whom there is not satisfactory coordination between the three muscle tendon portions. This would explain why the tendon often ruptures in untrained athletes.

Present series

The series of cases of partial rupture of the Achilles tendon numbering altogether 24 can be divided into two groups one comprising 11 active champion athletes between 19 and 29 years old who were training almost daily all the year round. The other group consisted of 13 athletes including one woman whose ages ranged from 38 to 65 years. The majority of the latter group had never given up sports completely. Several of them were still very active taking part in for instance orienteering races and the Vasa Ski Race (sking competition over a distance of 85 km).

The first group cannot be regarded as representative of Arner & Lindholm's series as all of them were in their most active period of athletics. Four were or had recently been members of the Swedish international athletic team the youngest one 19 years old being a member of the junior team and considered to be one of our most promising medium distance runners. The others were champion ice hockey players footballers and track and field athletes — medium distance and long distance running. The mean age was 25 (24.8) years. It was of course difficult to establish the exact time that had elapsed between the injury and the operation at which specimens for histological examination were taken. Some of the patients reported several injuries. In one case however the exact interval of 5 days could be established. After careful history taking and analyses

Trauma

The Achilles tendon can be ruptured by direct or indirect violence. It is believed that rupture can occur when the violence is applied at right angles to a tense tendon (Kolb & Salem). Indirect violence is considered to be the more common cause. Arner & Lindholm, in analysing the causes of complete rupture, distinguished between three main types of indirect violence.

1) Pushing off with the weight-bearing forefoot flexed in a plantar direction while extending the knee joint, for instance at the start of a sprint, in running and in some types of jumps. In this coordinated movement the calf muscle is maximally contracted,

2) Sudden and unexpected violent dorsiflexion of the ankle when the foot is in an intermediate position for instance in slipping on a stair, or stumbling into a hole, the patient falls forward and the heel sinks down suddenly. In this type of violence the calf muscle is usually moderately contracted and becomes maximally contracted in the sudden reflected and uncontrolled movement.

3) Violent dorsiflexion of the foot flexed in a plantar direction for instance on jumping or falling from a height. The calf muscle is strongly contracted and the sudden violence to the foot leads to marked stretching of muscle and tendon.

The Achilles tendon, being one of the strongest tendons of the body, takes a load of about 240 kg at ordinary walking and of about 600 kg at running. The load may amount to 900 kg at very swift running (Carlsoo 1968). Arner, Lindholm & Orell (1959) in their series of 74 cases of complete rupture examined histologically noted degenerative changes in the tendon in all the cases even in those of the patients operated on only a few hours after the injury (see also Davidsson 1956). They attributed the histological changes to impaired blood supply. Angiographic and microangiographic studies by Lagergren & Lindholm (1959) have shown that the most frequent site of rupture of the Achilles tendon is the segment least vascularized namely 2—3 cm above the insertion of the tendon. Arner & Lindholm give the following explanation of the Achilles tendon rupture. Training and increased activity of a muscle lead to hypertrophy and increased vascularisation of muscular tissue (Petron Sjostrand & Sylvén 1936), and probably also of tendon tissue during an athlete's active years. If these are followed by inactivity degenerative changes will occur in the tendon tissue with resulting impaired tensile strength. Ricklin (1962) states that the elasticity diminishes rapidly after age 30 with progressing

Pathology and pathogenesis

The histological changes in subcutaneous complete rupture of the Achilles tendon have been described earlier by for instance Kolb & Salem in 1953 (6 cases) Davidsson in 1956 (5 cases) Orell in 1958 (14 cases) and Arner Lindholm & Orell in 1959 (74 cases) The last named authors found characteristic degenerative and necrotic changes in the tendon tissue in all their cases (see page 20)

Own investigations*

The histological findings are recorded in Table V The *champion* group (Table II) includes one patient (no 18) with a partial rupture that was examined only 5 days after the injury Gross examination showed relatively extensive haemorrhage along the rupture ends The histological picture of the resected rupture ends was that of devitalized tendon tissue with altered collagen stainability and non stainable endoplasm areas Minimal inflammatory cell infiltration was seen in a few places around the vessels as well as slight fibrin exudation There were virtually no formation of granulation tissue and no signs of newly formed tendon like granulation tissue

In the rest of the patients in the *champion* group — irrespective of the time interval between injury and operation — the histological examination of the resected rupture ends showed partially devitalized tendon tissue with obliterated fibrin structure and in places fraying of the collagen bundles altered stainability and decolourized poorly stainable or non-stainable endoplasm areas To the devitalized tendon tissue were attached fine or coarse streaks of loose granulation tissue rich in collagen and of a thin wavy structure that deviated from the collagen structure of normal tendon tissue The tendon like granulation tissue in cases 6 and 19 in which the time interval between injury and operation was 12 months and 8 months respectively was highly vascularized and inflammatory infiltrates were seen around the vessels in some places there were also

*The histological examinations were carried out in cooperation with Hans Nordenstam, prosector at the Department of Pathology Serafimerlasarettet

of the reported traumata, the approximate time interval could be fairly well ascertained

Some data in the most active group are set out in Table II Table III shows data from the athlete group, but it should be noted here that most of these patients had, in fact, never given up sports entirely

In those cases in which a long time had elapsed between the injury and the author's first examination of the patients, it was difficult to establish the nature of the trauma With due reservations, the distribution of the causal violence, according to the Arner-Lindholm scheme (their group 3 not being represented), can be listed as follows

<i>Group 1</i>	<i>14 cases</i>
<i>(start of sprint, running)</i>	<i>{nos 1, 2, 5, 7, 8, 13, 14, 16, 17, 20, 21, 22, 23}</i>
<i>Group 2</i>	<i>10 cases</i>
<i>(slipping)</i>	<i>(nos 3, 4, 6, 9, 10, 11, 12, 15, 18, 19)</i>

The series includes one case in which direct violence was applied to the tendon In the rest of the cases the patients were able to specify one or several similar types of indirect violence as the cause of the rupture

Fig 3 Devitalized tendon tissue partly with complete absence of stainable cell nuclei

Summary

The histological changes both in the champion group with a mean age of 25 years and in the athlete group with a mean age of 48 years were characterized by devitalized tendon tissue with altered collagen stainability frayed fibrous structure to which attached granulation tissue converted into more or less tendon like connective tissue Newly formed granulation tissue was seen in 14 cases (see Table V) Old tendon like

large areas of loose granulation tissue poor in collagen. Lymphomonocytic cell infiltration, mainly perivascularly, was seen in all the cases. The degree of inflammation was recorded as minimal to moderate. Some surfaces were coated with a fibrin-like albumin containing mass (nos 1, 14, 18, 23, and no 12 in the athlete group).

In the two cases with the longest history (nos 6 and 19) histological changes were also seen in the peritenon. The excised peritendinous tissue consisted of fatty tissue showing transformation into newly formed granulation tissue, fairly rich in collagen and of a wavy structure. Inflammatory changes were seen around the vessels. There was no true tendon sheath structure. No synovial membrane was visible. The picture resembled mainly that of peritenon with fatty tissue and newly formed granulation tissue of tendon like appearance.

The histological findings in the *athlete group* (Table III) were largely consistent with those in the *champion group*, in that 'the collagen fibres were in places interrupted by granulation tissue, which indicates that partial rupture must be present' (case 9).

In 4 cases (nos 3, 11, 17, and no 22 in the *champion group*) defined areas of necrosis were found in the devitalized tendon tissue. Suggested dystrophic calcification was noted in the necrotic areas. Parts of the areas were almost tophus-like in appearance (nos 17 and 22).

In patient no 17, who had a possibly 10-year old rupture, a history of achillobursitis, and recurrent symptoms of trouble with the tendon 2 months before operation, histological examination showed not only the usual partial devitalization of tendon tissue but also profuse old and new formation of granulation tissue. Here and there mainly in this granulation tissue, the collagen showed changes most closely resembling myxomatous degeneration. Foreign-body reaction was seen in these areas. This patient had not received any form of steroid therapy, nor any other specific treatment.

In view of the fact that several of the patients had earlier received local steroid injections and that in a few cases operation revealed a few yellowish white deposits in the peritenon, the specimens were also examined for the presence of foreign body granulomas or deposits of foreign matter but no such lesions were found in any of the cases. Analysis of the observed deposits at hormone and chemical laboratories did not show any steroid substance.

Inflammatory monolymphocytic cell infiltration perivascularly was seen in all the cases of this group, minimal in the fresh ruptures and more profuse in the older ones. Ingrowth of vessels was occasionally seen in the devitalized tendon remnant.

Symptomatology

Considering the pathology (see the foregoing) the patient would be expected to suffer tenderness over the rupture site and pain on weight bearing. It will be seen from Table VI that swelling, tenderness and pain on weight bearing were in fact present in virtually every case. These symptoms occur however in several pathological conditions involving this region. The almost invariably experienced stabbing or pricking pain on suddenly increased activity and weight bearing is more specific to the partial rupture. The pain is probably associated with stretching of the injured tissue.

Some patients complained of stiffness of the tendon in the morning and after they had been sitting still for a long time and also of occasional aching at rest. The stiffness was most marked in cases of fresh rupture and was then probably attributable to oedema and swelling of the ruptured area. In cases of older rupture there was also profuse formation of granulation tissue and adhesions to the peritenon.

In 17 of the present cases the patients complained of weakness of the calf and difficulties in rising on the toes or in controlling the foot when attempting to run. The feeling of weakness can be associated with the loss of function of parts of the muscle tendon unit and varies with the extent of the rupture. The limiting effect of pain could also be a contributing factor.

The cause of the condition as stated by the patient was trauma for instance slipping or the like during athletic exercise (11 cases). Some of the patients regarded the injury as insignificant and not worth mentioning at the time; some had even forgotten all about it by the time they appeared for the first examination. But after careful questioning it was usually possible to discover some insult in the form of excessive weight bearing. In most cases this had been accompanied by the afore mentioned shooting, stabbing, pricking or jarring pain or a sensation of being struck with a whip (23 cases). Some patients described the pain as intense but to many it appeared slight and at first of no importance.

In 8 cases the patients reported a sensation of snapping or tearing of the Achilles tendon. Such an experience is in fact consistent with the

granulation tissue was found in all the cases, except no. 18 with a partial rupture of only 5 days' standing. In all the cases there was minimal to relatively profuse perivascular lymphomonocytic cell infiltration as evidence of post-traumatic inflammation.

Acute inflammatory cell infiltration was seen in 7 cases (nos. 4, 10, 11, 14, 17, 19, and 20) and chronic cell infiltration in all the 24 cases.

As regards the time for the histological changes to develop from the acute to the chronic stage, the limit can probably be fixed at about 7 days. After this time it was not possible to determine the age of the rupture. Chronic changes were the predominating histological findings throughout the series.

No vascular changes were demonstrated in the present cases.

In those cases in which the rupture ends are not distinctly visible macroscopically the histological changes associated with a partial rupture of the Achilles tendon may be defined as follows. Devitalization of the tendon tissue, in which the collagen fibres in places have been replaced by granulation tissue.

Diagnosis

As was mentioned earlier many authors doubt the existence of partial rupture of the Achilles tendon Kolb & Salem state, however that tiredness and insignificant pain are often the only symptoms of partial rupture and that therefore the diagnosis is sometimes very difficult if not impossible

In the present series of cases the diagnosis was based on

- 1) the case-history
- 2) clinical examination
- 3) X ray examination
- 4) electrophysiological examinations

The case-history

Data relating to the patient's physical activity are of importance to the diagnosis as are information concerning lengthy periods of hard training on surfaces that lead to greater demands being placed on the Achilles tendon such as hard icy roads wooden floors etc Newly added items on the training programme and any injuries are analysed

The subjective symptoms have been described in the foregoing (Page 29) and are shown in Table VI The stabbing jarring or pricking pain in the Achilles tendon and the feeling of a tear or an audible snap in the region of the tendon give rise to strong suspicion of partial rupture of the Achilles tendon

Clinical examination

The findings by clinical examination are set out in Table VII On inspection of the tendon region with the patient standing erect turning his back to the examiner and with equal weight bearing on both feet the injured tendon appeared locally or to the whole of its extent *increased in width* in 23 cases *Ecchymoses* on the back of the heel extending below both malleoli were seen in the three cases in which the rupture had occurred 1—5 days before the examination When the patient was standing

true course of events. When distinct it should give rise to strong suspicion of rupture.

In most cases the tendon injury did not interfere with the patient's work. Only patient no. 3, an electrician, suffered limitation of movement in his work, especially on climbing ladders, because of reduced muscular strength in the plantar flexors of the foot.

The objective symptoms are listed in Table VII. As in most cases they were not demonstrated before careful clinical examination they will be described under that heading (see the following).

of the respective belly Thompson's (1960) test performed with the patient standing on all fours elicited normal plantar flexion in all the cases though with slightly reduced muscular strength in 2 cases when resistance was applied by the examiner's other hand. Increased dorsal extension in the talocrural joint as a sign of lengthening of the muscle and tendon was noted in several cases. Greatly increased dorsal extension (to 5–15° more

Fig 5 Partial rupture of gastrocnemius component of left Achilles tendon. In the right uninjured leg the contracted gastrocnemius muscle bellies are distinctly seen, muscle tone normal on palpation. The injured leg shows no typical contraction of the gastrocnemius muscle bellies, palpable reduced muscle tone.

on tiptoe with equal weight bearing on both forefeet more or less distinct *muscle atrophy* was seen in 14 cases in 3 involving the medial and in 6 the lateral gastrocnemius belly and in 5 being generalized atrophy of the triceps surae. The circumference of the calf was 1.5—2 cm less than that of the healthy leg. In all the cases in which distinct muscle atrophy was noted at the examination palpation was believed to reveal reduced *muscle tone*.

of the respective belly Thompson's (1960) test performed with the patient standing on all fours elicited normal plantar flexion in all the cases though with slightly reduced *muscular strength* in 2 cases when resistance was applied by the examiner's other hand Increased dorsal extension in the talocrural joint as a sign of lengthening of the muscle and tendon was noted in several cases Greatly increased dorsal extension (to 5—15° more

than normal) was present in 8 cases. It was noted in patients with ruptures that involved a relatively large section of the tendon and were of relatively long standing. An increase of dorsal extension to a few degrees more than normal was seen in 5 patients, but such an increase would be within the limits of normal differences in the range of movement between the right and the left ankle joint. With the weight-bearing at walking etc., after a relatively deep-going partial rupture the thin remaining part of the tendon and its muscle portion will be gradually and increasingly stretched and permanently lengthened, which would explain the increase of dorsal extension.

Palpation of the Achilles tendon was done with the patient supine, the foot flexed in a plantar direction and the knee flexed, and with the patient lying prone or standing on his knees, the foot in mid-position and standing on his toes. The tendon could thus be palpated right through relaxed, moderately tense, and maximally tense. A *fusiform thickening* of the Achilles tendon was noted in 23 cases, over an area 2—6 cm (18 cases) and 6—10 cm (6 cases) above its insertion, and corresponding to the rupture site. The thickening involved the whole tendon in 4 cases, in some mainly the medial, the dorsal, or the lateral portion, with marked tenderness on palpation, in 3 cases there was distinct fluctuation. In all the patients (24 cases) palpation of the ruptured tendon revealed an indurated section that was firmer than the normally relatively soft elastic consistence of uninjured tissue. Suspected *dents or small defects* in the tendon contour were also palpated in 9 cases and some *irregularity* in the contour or the peritenon in 2 cases.

X-ray diagnosis

The Achilles tendon is surrounded by loose tissue mostly fatty tissue and can therefore be seen in a radiograph. The radiographic appearance of the Kager triangle, described by Kager (1939) has been regarded as diagnostic of subcutaneous complete rupture of the Achilles tendon. Arner, Lindholm & Lindvall (1959) state that deformation of this triangle, which in lateral views is bounded by the Achilles tendon, the calcaneus and the deep flexor tendons, is pathognomonic for complete subcutaneous Achilles tendon rupture, when the tendon contour curves away dorsally from the posterior surface of the calcaneus between the insertion of the tendon and the upper margin of the corner of calcaneus and then proximal to this point deviates ventrally.

After subcutaneous partial rupture of the Achilles tendon a change in "Kager's triangle" also occurs in some cases (see below at 3). By infiltra-

Fig 6 X ray findings in Case 19

Right Normal Achilles tendon of contralateral side with Kager's triangle displayed as a triangular light part the base formed by the upper margin of the calcaneus and the side by the central contour of Achilles tendon and the dorsal contours of the deep flexor tendons

Left Achilles tendon partially ruptured centrally Kager's triangle reduced and deformed by tendon thickening and soft tissue infiltration and the tendon contour irregularly outlined against the fatty space Small areas of calcification are also seen in the soft tissue space

In 3 patients with injuries of both Achilles tendons simultaneous X ray of contralateral tendon showed local thickening but no other abnormalities

tion into the fatty space it becomes more or less symmetrically narrowed or reduced in comparison with that on the contralateral uninjured side

X-ray examination was performed in 19 cases The observed changes are recorded in Table VIII

The following changes were seen

- 1) Local more or less extensive, thickening of the tendon (16 cases)
- 2) Tendon contour less distinct than normal and irregularly outlined against the fatty tissue (10 cases)
- 3) Soft-tissue space infiltrated (11 cases), in some cases round the whole tendon, in others dorsally or only ventrally

These findings proved to be of value in locating the rupture site especially when the first superficial inspection of the exposed tendon at operation did not show any obvious change Exposure of the section of the tendon corresponding to the part showing radiographic changes revealed a

partial rupture situated ventrally in the cross section of the tendon (case 24)

Soft tissue X ray showed in 2 cases (nos 2 and 19) minor areas of calcification ventral to the Achilles tendon which were interpreted as calcification of haematomata after rupture. In one of these cases (no 19) in which the tendon appeared intact on inspection incision of the tendon revealed a central rupture with calcium incrustation both in the proximal and in the distal rupture ends.

The contour could not be seen in 1 case (no 14) and therefore the rupture could not be assessed radiographically.

Soft tissue X ray is an important part of the examination in cases of suspected partial rupture of the Achilles tendon. In some cases in which neither the clinical nor the electromyographic examination yielded any conclusive evidence of partial rupture the X ray findings provided a valuable basis for the decision whether or not to operate.

Electrophysiological examinations*

So far as is known electrophysiological studies of partial tendon ruptures in man have not been described earlier. A preliminary report of the studies in the present cases has been published (Persson 1967) and a more detailed account will be published elsewhere (Persson & Ljungqvist in the press).

The studies comprised

1 *Electromyographic recording*

of voluntary activity using concentric needle electrodes in the triceps surae. Cases 2-24 were examined by this method. The amount of such activity was compared between corresponding electrode positions in the healthy and the affected leg and between the lateral and medial gastrocnemius bellies and the soleus muscle of the same leg. To activate the muscle under examination the patient was told to stand on his toes bearing the weight of the whole body on the leg to be examined.

In cases of partial rupture the amount of motor unit activity was found to be reduced in the muscle portion whose tendon had been torn. The pattern of activity was also changed. Most of the action potentials recorded were of small or medium amplitude whereas the large potentials which always appear at moderate to strong contraction were lacking (see Fig 7 A).

* Performed in cooperation with Ass. Prof. Anders Persson, Department of Clinical Neurophysiology, Karolinska Sjukhuset.

Fig 7
CASE 24 EMG recordings in a patient with partial rupture of the tendons of the lateral gastrocnemius and soleus muscles

A EMG from lateral (upper tracing) and medial (lower tracing) gastrocnemius belly
B Contraction curve and **C** H reflex from the affected (upper tracings) and the healthy leg
A: shortened contraction time due to rupture of the soleus tendon and deformed contraction curve due to gastrocnemius rupture

Organic lesion of the peripheral or central nervous systems was not present in these cases. Yet, as was evident from the electromyograms the patients were unable to perform maximal activation of the muscles. A similar functional disturbance has been shown by Blom & Hagbarth (1966) in muscles of amputation stumps, where the tendons or muscles had been divided. In their cases as well as in ours there was probably a changed proprioceptive inflow from the muscles, which led to a disturbance of the feed back mechanisms. This would be the primary cause of the functional paresis. Pain played no significant part in these cases, none of the patients reported pain from the tendon region on activation of the muscle during the examination. Moreover, inhibition by pain could hardly have produced the observed asymmetry of the electrical activity.

2 Analysis of the "H-reflex"

in the gastrocnemius and soleus muscles. This is a proprioceptive muscle reflex mediated via a two-neuron arc (Hoffmann 1922, Magladery et al., 1952), thus being of the same type as the common ankle jerk but, unlike the latter, it is elicited by electrical stimulation of the posterior tibial nerve and not by stimulation of the stretch receptor by tapping the tendon. The magnitude of the reflex response may be said to be a measure of the excitability of the motoneuron. It was recorded electromyographically with surface electrodes over the various portions of the triceps surae. The H-reflex was studied preoperatively in cases 10–24.

The results showed that a rupture that involves the tendon of the gastrocnemius alone, medially or laterally, has no significant influence on the H-reflex. After ruptures of the soleus tendon on the other hand isolated or combined with partial or total rupture of the gastrocnemius there is a significant increase of the H-reflex, the amplitude of the response being 2–3 times larger than in the healthy leg (Fig. 7 C). Such abnormally increased reflexes were noted in cases 18, 19, and 24 and in 2 cases of total rupture. To judge from the results of our studies of total Achilles tendon ruptures, the increase of the reflex does not occur until some time (a few weeks) after the rupture.

The phenomenon may seem paradoxical after a tendon rupture the muscle is less stretched than normal and so it would be expected that the muscle spindles should also be lax and that their stimulating influence on the motoneurons of the muscle should be reduced. A decreased H-reflex could therefore have been expected. By experiments on animals (Kozak & Westerman 1961) it has been shown however that tenotomy is followed by increased afferent activity from the muscle concerned possibly caused

A further 100 patients with long standing symptoms located in the region of the *Achilles tendon* (such as pain, tenderness and swelling of

by a compensatory increase of the activity in the gamma-motoneurons of the muscle, which results in an increase of the monosynaptic response

The observation that in man the reflex is increased after soleus but not after gastrocnemius rupture may be accounted for by the fact that the soleus muscle is of predominatingly slow "tonic" type

3 *Analysis of the isotonic contraction curve of the calf muscles*

Muscle twitching was elicited by electric stimulation of the posterior tibial nerve and the plantar flexion of the foot was recorded with a capacitive transducer (Dickinson 1950), which did not interfere with the movement. This examination was made in cases 2—24. The contraction time (the time from the foot of the curve to its peak) was measured and the shape of the contraction curve was analysed. The contraction time for a mixed muscle is of course determined by its slowest component. Accordingly, a significantly shortened contraction time was recorded in cases of rupture of the soleus tendon (Fig. 7 B). Partial rupture of the gastrocnemius tendon, on the other hand, caused deformation of the contraction curve (Fig. 7 B) and prolongation of the contraction time.

The results of the preoperative electrophysiological examinations are set out in Table IX, which also shows the rupture site as revealed by operation. It will be seen from the table that in 19 out of 23 cases the conclusions drawn on the basis of these examinations with respect to the extent and localization of the partial rupture were in very good agreement with the findings at operation. In a further case (no. 6) re-examination of the film showed that the E M G picture clearly indicated lateral rupture that is, established the correct site. Insufficient experience with the method of examination accounts for the uncertainty in the initial interpretation of the findings in this case.

In cases 8 and 9, in which the electrophysiological diagnosis was in doubt, the rupture involved the whole or part of the soleus tendon. When these patients were examined, analysis of the H-reflex had not yet been introduced, nor were any attempts made at using the needle electrode for selective recording from the soleus muscle. These factors would explain the failure.

The reason why the rupture site in case 15 could not be established in spite of repeated examinations is obscure.

All the patients were examined on several occasions postoperatively. At check ups 3—6 months after operation E M G was normal in all the cases.

The method of electrophysiological diagnosis used in the 23 cases presented in Table IX has since then been applied in a further 15 cases of

Figures in parentheses = Rupture involved only very small part of fascicle or portion of tendon

operatively verified partial rupture of the Achilles tendon. In every one of these 15 cases the extent and localization of the rupture could be correctly predicted on the basis of the results of the electrophysiological examination.

A further 100 patients with long standing symptoms located in the region of the Achilles tendon (such as pain tenderness and swelling of

varying degree of severity) have been examined. No electrophysiological changes of the type found in partial rupture were demonstrated in any of these cases. The patients who were not operated upon improved on conservative treatment and the condition was classified as "tendinitis".

In another 2 cases E M G showed slight asymmetry of voluntary activity which, in itself, might have been compatible with a small partial rupture. The H reflexes and contraction curves were normal. At a check up after some weeks E M G was normal in both cases. By then, the patients were also symptom-free. The question whether these patients had had small partial ruptures cannot be answered. Clinical manifestations and other observations argued against this possibility.

Differential diagnosis

As will be seen from the description of the symptomatology and diagnosis of the partial Achilles-tendon rupture (see Tables VI and VII), the patient's history and the clinical findings are not pathognomonic. The condition can be confused with many other conditions affecting the Achilles tendon and surrounding tissue, such as complete Achilles tendon rupture, tendinitis, peritendinitis, calcaneal bursitis, periostitis, and insufficiency fractures. These conditions can often be differentiated clinically from a partial tendon rupture by the presence in the latter case of, especially, the jarring pain, feeling of weakness, and muscle atrophy. Further, the increased dorsal extension in the ankle joint is absent in all the other conditions except complete rupture. In most cases the electrophysiological examinations will help in differentiating with certainty a partial rupture from the above mentioned conditions.

In complete rupture of the Achilles tendon the plantar flexion of the foot at Thompson's test is absent. This absence is pathognomonic and therefore, complete rupture need not be confused with partial rupture.

The partial Achilles-tendon rupture can sometimes be difficult to distinguish from *achillotendinitis* whether the latter is in an acute or a chronic stage. Antiphlogistic medication has usually a distinct beneficial effect on the tendinitis provided that the Achilles tendon is not subjected to any form of increased activity during the treatment. "Tennis leg" (Arner & Lindholm 1958) — rupture of the medial gastrocnemius aponeurosis and the muscle belly — can often be confusingly like a partial Achilles-tendon rupture, as the pain can primarily be located in the calf and the Achilles tendon both in partial rupture and in "tennis leg". But in "tennis leg" palpation will reveal transverse distinct local tenderness.

and diastasis or induration over the medial gastrocnemius belly E M G may also show some abnormalities in these cases because of limitation of movement by pain but these changes are not characteristic of the injury unlike the E M G findings in partial rupture

Another painful condition affecting the Achilles tendon region and accompanied by symptoms similar to those of partial rupture is *peritendinitis* — involving not only the Achilles tendon but also the tibialis posterior and the peroneal tendons Crepitations occur in peritendinitis The tenderness on palpation is also more extensive and less distinctly localised than in the partial rupture *Bursitis* of the subcutaneous Achilles bursa and of the calcaneal Achilles tendon bursa in particular can cause pain radiating ventrally proximally along the Achilles tendon Bimanual palpation often reveals fluctuation and this can be further verified by aspiration of exudate on puncturing the bursa

A possibility that must not be forgotten is that in athletes *periostitis* of the tibia and fibula as well as the not uncommon *insufficiency fractures of the fibula* can give rise to pain — which is initially difficult to locate — in the back of the lower leg and the Achilles tendon region Palpation and X ray examination of the lower leg and E M G will usually be diagnostic in differentiating these conditions from partial Achilles tendon rupture Ankle sprain with hyperextension strain and injury of the posterior part of the joint capsule should also be considered in the differential diagnosis

Treatment

When an Achilles tendon is torn, the extent of the rupture can vary, from a clinically insignificant tear to complete rupture with complete loss of tendon function. Cases of the former type require no treatment, whereas those of the latter result in considerable disability, unless the function of the tendon is restored by surgery. The ruptures here designated as partial fall somewhere between these two extremes.

In those cases in which the results of investigation argue for the presence of relatively small ruptures the correct procedure would be to try first a period of rest and symptomatic treatment. If the patient still complains of distressing trouble or objective symptoms persist at the end of this period, operation should be performed. If the symptoms are severe and the rupture is assessed as extensive, the primary treatment should be by operation.

Conservative treatment

Because of the way in which it was collected the present series of cases does not include patients with small ruptures and mild transient symptoms. Most of the patients (13 cases) had undergone prolonged (6—18 months) conservative therapy consisting of rest, short-wave, ultrasonic-wave and X-ray treatment, and had received antiphlogistics (Tanderil® Butazolidin®), local steroid and heparin injections without any noticeable effect. Immobilization in plaster for 3—4 weeks had been tried in 3 cases but produced no improvement. As soon as the Achilles tendon was allowed weight-bearing beyond ordinary walking symptoms were noted in the form of tenderness, swelling and shooting or stabbing pain.

Considering the pathology of the injury (see the following) it may be said that restitutio ad integrum by conservative treatment is impossible. There will remain for instance the elongation of the tendon which has been described above. The conservatively treated patients in this series also had subjective or objective symptoms of varying degrees of severity which indicated operation.

Operative treatment

The aim of the operative treatment was to restore the muscle tendon relation so as to re establish as near as possible its normal function

The operations were carried out under ether anaesthesia (6 cases) extradural anaesthesia (12 cases) spinal anaesthesia (5 cases) or with blocking of the sciatic nerve (1 case) A bloodless field was obtained by compression of the thigh with a pneumatic tourniquet inflated up to a pressure of 550 mm Hg The patient was lying prone on the operation table

The Achilles tendon was exposed with a medial curved incision from the insertion of the calcaneus towards the border between the medial and the lateral gastrocnemius bellies The peritenon was divided in the mid line from the calcaneal insertion After the peritenon had been divided the changed rupture area could be directly observed in 17 cases and also in some cases in which the rupture ends were covered with granulation tissue When the granulation tissue had been removed by blunt dissection or excision the rupture ends were clearly seen No definite pathological changes were seen in 7 cases after the peritenon had been divided The tendon surface looked normal on the whole The guidance provided by E.M.G. and X ray as to the rupture site proved valuable in these cases Careful palpation manually and by means of instruments over the suspected sections revealed softer or firmer parts of the tendon which in some instances showed suggested fusiform thickening A longitudinal incision of the changed part disclosed at a depth of a few millimetres the following types of pathological changes

- a) Cavities in which the ends of the ruptured tendon were seen lying retracted from one another and coated with haemorrhages and fibrin deposits (3 cases)
- b) Soft granulation tissue without tendon structure (2 cases) further exposure revealed the retracted tendon ends and the diastasis filled with the contour less granulation tissue
- c) Induration and adhesions ventrally on the tendon (2 cases) which concealed ruptures situated ventrally and centrally

The appearance of the rupture varied greatly but the following types could be distinguished*

*The records are taken from the tendon segments mainly affected by the rupture

	Transverse rupture	Oblique longitudinal rupture
Medial gastrocnemius portion	3 cases	3 cases
Lateral gastrocnemius portion	6 cases	8 cases
Central soleus portion	3 cases	1 cases
Total	12 cases	12 cases

After the rupture had been located, granulation tissue and devitalized tendon tissue was excised. The continuity of the tendon was then restored by various methods, as seen in Table X. End-to-end suture was used in 8 cases. The operation was especially difficult in those cases in which the rupture was of long standing and the rupture ends were widely separated while at the same time some lengthening of the non-ruptured tendon portion had occurred. By longitudinal incision into the border between the ruptured and the intact tendon portion the retracted rupture ends were mobilized to assure as satisfactory apposition as possible. In 2 cases in which this could not be done the surgeon divided the intact non-ruptured tendon portion and sutured it across the ruptured ends for reinforcement so as to assure adequate apposition. In 2 cases the tendon was greatly thickened because of granulation tissue and devitalized tendon tissue centrally. After excision the tendon was of normal thickness or slightly thinner than normal. In these cases we did no more than apply suture round the cystic cavity with its exposed tendon walls and draw it sufficiently tight for the excised tendon walls to unite closely.

In longitudinal oblique ruptures and central ruptures side to side suture was used in 7 cases.

Suture and plastic repair with a flap were performed in 5 cases. The flap was taken from the common tendon aponeurosis where it appeared most viable. Thus, if the rupture was laterally situated the flap was taken from the medial side and swung over laterally to cover the defect. With a medially situated defect the procedure was the reverse. Loose connective tissue and any hardened tissue dorsally on the flap was removed so that a fresh tendon surface was obtained. In order that the tendon contour would be as even as possible, the flap was not unlike Silfverskiöld's or Lindholm's technique rotated 180°, as this often results in more or less marked thickening of the tendon contour corresponding to the rotation area. The flap was instead turned down without rotation distally with the dorsal freshened up surface over the tendon defect and sutured.

TABLE X
Method and result of operation

Method of operation	Number	Excellent	Good
End to end suture	8	8	
Side to side suture	7	7	
Suture plus plastic repair with flap	5	5	
Suture plus plastic repair with plantaris tendon	4	3	1
Total	24	3	1

Suture and plastic repair with the plantaris longus tendon were used in 4 cases in which excision of devitalized tendon and granulation tissue had given a larger longitudinal tendon defect centrally medially or laterally. The plantaris longus tendon which in all the cases extended medially was loosened at its insertion on the calcaneus and sutured into the defect. When the defect was situated centrally or laterally it was sutured after tunnelling from the medial side into the defect tendon area.

All the tendon sutures were made with synthetic suture material (supramid). Peritenon was sutured with catgut which was not used furthest distally however as the tension will be too great at this point when the foot is flexed more or less markedly in a plantar direction. After skin suture the foot plus lower leg was immobilized in plaster with the foot moderately or in some cases markedly plantar flexed to ensure least possible tension in the suture area.

The patients could be discharged from hospital on the 3rd—7th post operative day. Before discharge they started to walk about on crutches. On discharge they were instructed to carry out toe exercises in the plaster cast and quadriceps exercises. Three weeks after discharge the patient was recalled for removal of the plaster and the sutures. A new full lower leg plaster cast was applied the plantar flexion of the foot being reduced as much as possible. As plantar flexion to 10—15° was used in most cases it was sometimes necessary to build up the heel slightly. Thereafter the patient was allowed to train walking gradually without crutches. The plaster was removed 4—7 weeks after operation and the patient was given a cork heel 1.2 or 3 cm thick to wear inside the heel of the shoe for the first two weeks. Remedial gymnastics consisting of active exercises of the ankle joint and strengthening exercises of the lower leg and thigh

muscles, were started on the day of plaster removal. They were continued until the range of movement in the talocrural joint was normal after 1–2 months. The patients returned for outpatient check-ups 1–2, 3, and 12 months after plaster removal.

Complications

No serious complications occurred. Apart from transient wound secretion without infection (case 19) and slight irritation of the skin over an area of one cm due to a loosened catgut suture (case 5), all the operation wounds healed by first intention. In 1 case (no. 13) a subcutaneous haematoma or seroma developed after removal of the plaster and had to be punctured four times. However, this did not prevent the patient from starting gradual training 4 months after operation. Some tightness of the gliding tissue round the Achilles tendon and the operation scar was noted in 1 case (no. 4) for the first 4 months after removal of the plaster. A relatively slight tenderness over the grafted area was present for the first few postoperative months in some of the plastic-repair cases.

CASE 8 Dorsal — medial rupture

a) Rupture ends enclosed in hardened callous granulation tissue incision for some distance in the mid line

b) After excision of granulation tissue and exposure of the distally rounded off and the proximally plat rupture end

muscles, were started on the day of plaster removal. They were continued until the range of movement in the talocrural joint was normal after 1—2 months. The patients returned for outpatient check-ups 1—2, 3, and 12 months after plaster removal.

Complications

No serious complications occurred. Apart from transient wound secretion without infection (case 19) and slight irritation of the skin over an area of one cm, due to a loosened catgut suture (case 5), all the operation wounds healed by first intention. In 1 case (no. 13) a subcutaneous haematoma or seroma developed after removal of the plaster and had to be punctured four times. However, this did not prevent the patient from starting gradual training 4 months after operation. Some tightness of the gliding tissue round the Achilles tendon and the operation scar was noted in 1 case (no. 4) for the first 4 months after removal of the plaster. A relatively slight tenderness over the grafted area was present for the first few postoperative months in some of the plastic-repair cases.

CASE 11 Medial rupture

c) Lateral intact tendon port on and medial rupture ends

d) Ach illes tendon sutured us g a flap from lateral port on of tendon.

CASE 11 Medial rupture

a) Granulation tissue and hardened tendon like tissue partly removed over rupture ends

b) Rupture ends exposed

CASE 11 Medial rupture

c) Lateral intact tendon portion and medial rupture ends

d) Achilles tendon sutured using a flap from lateral portion of tendon

CASE 19 Central soleus rupture
a) Achilles tendon exposed

b) Incision into palpably harder part

CASE 19 Central rupture

c) Central cystic cavity with granulation tissue haemorrhages and fibrin deposits

d) Central rupture ends after excision of granulation tissue

CASE 19 Central soleus rupture
a) Achilles tendon exposed

b) Incision into palpably harder part

CASE 18 5 day old central — medial rupture

CASE 22 Multiple small medial ruptures

CASE 10 Transverse rupture through the whole lateral tendinous portion of gastrocnemius

CASE 15 Rupture of soleus portion rupture ends rounded off distally about 1 cm from insertion of Achilles tendon on calcaneus

CASE 18 5 day old central — medial rupture

CASE 2 Multiple small medial ruptures

CASE 22 Medial rupture Plastic repair with plantaris longus tendon

CASE 24 Sutured rupture ventrally in lateral portion of gastrocnemius also slightly involving tendinous portion of soleus

Results

Kolb & Salem (1953) report that in their series of 2 operatively and 2 conservatively treated cases of partial Achilles tendon rupture relief of symptoms and normal tendon function were obtained in the two operation cases in spite of transient fistula formation. With the conservative treatment the end result was satisfactory in 1 case but as far as can be judged this patient had a rupture of the gastrocnemius aponeurosis — "tennis leg". In the other case in which the rupture involved the free portion of the Achilles tendon fatigability, muscle atrophy and tenderness on palpation were still present 4 years after the injury.

Conservative treatment

In the present series 13 patients had been treated conservatively for 6—18 months. Rest for 2—6 months and in 3 cases immobilization in plaster for 3—4 weeks had not led to improvement. Nor had X ray and short wave treatment seemed to improve the condition. Local steroid and heparin injections had caused only temporary alleviation of the symptoms. Every form of increased activity caused increased pain and swelling of the Achilles tendon.

Operative treatment

The length of stay in hospital was 3—7 days. The results after this period of time will be seen in Tables X and XI. The disability period was wholly dependent upon the patient's occupation. Three young university students were able to resume studies within 1—2 weeks after operation. Three office clerks returned to work after 3 weeks wearing walking plaster. Six patients returned to work within 6—7 weeks after removal of the walking plaster. Another 6 patients with more strenuous and active type of work returned to it within 2 months. Five patients with heavy or highly active type of work were unable to return to work for 3—5 months. The oldest patient (aged 65 no. 10) resumed half time work within 2 months.

CASE 22 Medial rupture Plastic repair with plantaris longus tendon

CASE 24 Sutured rupture ventrally in lateral portion of gastrocnemius also slightly involving tendinous portion of soleus

but, because of the special nature of his occupation, was not able to resume full-time work until 5 months after operation

The ability to walk on flat ground which of course is essential in most normal activities, was recovered within 7 weeks in most and within 2 months in all the cases

In the group of champion athletes all, excluding 2, resumed training activities in running, football, and ice hockey. Patient no 22 was able to do high jumps of 1.80 m but after hard sprint training he had diffuse pain from the non operated portion of the Achilles tendon. EMG at several check ups showed no abnormalities, however Patient no 14 did not resume his training activities, but the main reason was that he gained weight during the long period of rest and partly lost interest in champion athletics. All the patients in the athlete group resumed their sports activities, such as competing in the Vasa Ski Race, long distance running, orienteering, gymnastics, football, and handball.

Half the patients had fully recovered, subjectively and objectively, within 2 months of the operation and all of them had done so within 1 year.

Case 2 is an example of the ability of the Achilles tendon to take great loads. Once or several times each season for 3½ years this patient returned after periods of hard training with symptoms of over exertion in the form of synovitis of the knee joint, tenobursitis alternately of the right and the left trochanter and ankle sprain but without any complaints of trouble from the Achilles tendon after operation. Patient no 8 completed a 30 km competitive cross-country race 5 months after operation without any adverse reaction from the Achilles tendon.

It will be seen from the account of the results that the forms of conservative treatment used produced no beneficial effects. As was mentioned under Treatment conservative treatment by rest and heat may be

justified in cases in which the rupture is judged to be very small. If the result is not satisfactory or if such treatment is clearly unlikely to succeed operation should be performed.

The operative methods that were tried in these patients led to complete healing in all the cases within a reasonable period of time. With the above said exceptions the author therefore recommends operative treatment of partial rupture of the Achilles tendon.

Subcutaneous partial rupture of the Achilles tendon has been regarded as an unusual injury. Many authors have questioned its existence. Only in 3 or 4 of the published cases of partial Achilles tendon rupture can the diagnosis be considered confident. During a short period of time (1964—1967), however, using a new method of examination (by electromyography) I have been able to diagnose and treat by operation 24 such cases at the Department of Surgery, Serafimerlasarettet, Stockholm.

Subcutaneous partial rupture of the Achilles tendon refers here to a tear of a varying number of fibres in the free portion of the Achilles tendon, most of the fibres usually remaining intact. Clinically, the partial Achilles tendon rupture can be differentiated from complete rupture by Thompson's test — manual compression of the triceps-surae muscle belly — in that plantar flexion of the foot does not occur if the rupture is complete. Absence of this reflex is pathognomonic for complete rupture of the Achilles tendon.

The present series comprises 24 patients who had undergone operation for the injury at least 1 year previously. All of them engaged in some form of sport and the majority had sustained the injury during sports activities. The patients can be divided into two age groups: one of 19—29 years, including champion athletes alone, and one of 38—65 years, comprising various kinds of non-champion athletes and including the only woman patient.

Of the aetiological factors described in the literature, steroid injections and traumata played a part in this series of cases. The steroid injections were probably of no direct aetiological significance; they might have played a part by relieving the patients of the symptoms attending a small rupture or some other injury of the Achilles tendon and so allowed increased weight bearing on the tendon, thus being concerned in causing the clinically manifest rupture.

The nature of the trauma was analysed and it was found that the patients could be divided by the causal violence into one group (14 cases) in which the partial rupture had occurred at running and one group (10 cases) in which the insult was due to slipping or the like. The earlier

theories proposing that the subcutaneous complete Achilles tendon rupture occurs in athlete during periods of inactivity could not be verified in the group of champion athletes with partial ruptures who were all in their most active periods of athletics

The histological changes both in the champion athlete and in the athlete group were characterized by devitalized tendon tissue with altered collagen stainability, frayed fibrous structure to which attached granulation tissue converted into more or less tendon like connective tissue. Acute inflammatory cell infiltration was seen in 7 cases and chronic inflammatory cell infiltration in all the 24 cases. The histological changes associated with a partial rupture of the Achilles tendon may be defined as devitalization of tendon tissue in which the collagen fibres in places have been replaced by granulation tissue.

The diagnosis was based on the case history, clinical examination, X ray examination and electrophysiological examinations.

Data concerning lengthy periods of hard training on surfaces that lead to great demands being placed on the Achilles tendon are of great importance. Newly added items on the training programme and any injuries are analysed. Besides swelling, tenderness, stiffness and pain on weight bearing which also occur in tendinitis, the patients complained of stabbing, jarring or pricking pain in the tendon on suddenly increased activity and of weakness in the calf muscles. The pain and the weakness are probably symptoms specific to partial Achilles tendon rupture. Eight patients also reported a sensation as of a tear or an audible snap in the tendon region.

The clinical examination with the patient standing on his toes placing equal weight bearing on both forefeet showed more or less distinct muscle atrophy (14 cases) of one or both of the gastrocnemius bellies and reduced muscle tone there. Increased dorsal extension in the talocrural joint as a sign of lengthening of the muscle and tendon and palpable dents or small defects in the tendon contour should give rise to suspicion of partial Achilles tendon rupture.

X ray examination was performed in 19 cases and showed the following changes: 1) Local more or less extensive thickening of the tendon (16 cases); 2) tendon contour less distinct than normal and irregularly outlined against the fatty space (10 cases); and 3) infiltration into the soft tissue space (11 cases). Owing to this infiltration a change had also occurred in the Hager triangle which was seen symmetrically narrowed and reduced in comparison with that on the contralateral uninjured side.

The electrophysiological examinations showed

Summary

Subcutaneous partial rupture of the Achilles tendon has been regarded as an unusual injury. Many authors have questioned its existence. Only in 3 or 4 of the published cases of partial Achilles tendon rupture can the diagnosis be considered confident. During a short period of time (1964—1967), however, using a new method of examination (by electromyography) I have been able to diagnose and treat by operation 24 such cases at the Department of Surgery, Serafimerlasarettet, Stockholm.

Subcutaneous partial rupture of the Achilles tendon refers here to a tear of a varying number of fibres in the free portion of the Achilles tendon, most of the fibres usually remaining intact. Clinically, the partial Achilles tendon rupture can be differentiated from complete rupture by Thompson's test — manual compression of the triceps surae muscle belly — in that plantar flexion of the foot does not occur if the rupture is complete. Absence of this reflex is pathognomonic for complete rupture of the Achilles tendon.

The present series comprises 24 patients who had undergone operation for the injury at least 1 year previously. All of them engaged in some form of sport and the majority had sustained the injury during sports activities. The patients can be divided into two age-groups: one of 19—29 years including champion athletes alone, and one of 38—65 years comprising various kinds of non-champion athletes and including the only woman patient.

Of the aetiological factors described in the literature, steroid injections and traumata played a part in this series of cases. The steroid injections were probably of no direct aetiological significance; they might have played a part by relieving the patients of the symptoms attending a small rupture or some other injury of the Achilles tendon and so allowed increased weight bearing on the tendon, thus being concerned in causing the clinically manifest rupture.

The nature of the trauma was analysed and it was found that the patients could be divided by the causal violence into one group (14 cases) in which the partial rupture had occurred at running and one group (10 cases) in which the insult was due to slipping or the like. The earlier

turned to work within 2 months. The ability to walk on flat ground was recovered within 7 weeks in most and within 2 months in all the cases. All but 2 of the champion athletes resumed full training but these 2 carry on relatively high sports activities as do all the athletes. Half the patients had fully recovered subjectively and objectively within 2 months and all of them had done so within 1 year.

- 1) Reduction of the amount of motor unit activity in that part of the muscle with ruptured tendon,
- 2) Increased H-reflex response in cases of rupture of the soleus tendon in other cases normal H-reflexes,
- 3) Shortened contraction time in cases of rupture of the soleus tendon Increased contraction time and change of the configuration of the contraction curve in cases of rupture of the gastrocnemius tendon

As regards the differential diagnosis, the partial Achilles tendon rupture can be confused with complete rupture, tendinitis, peritendinitis, calcaneal bursitis, periostitis and insufficiency fractures of the fibula or tibia. In most cases the clinical and the electrophysiological examinations will help in differentiating with certainty a partial rupture from the above-said conditions.

Out of the 24 patients, the majority (13 patients) had undergone long term (6—18 months) conservative therapy consisting of rest, short wave, ultrasonic-wave, and X-ray treatment antiphlogistics (Tanderil®, Butazolidin®), local steroid and heparin injections, and immobilization in plaster without any noticeable effect.

The aim of the operative treatment was to restore the muscle-tendon relation so as to re-establish as near as possible normal function. After exposure of the Achilles tendon with a medial curved incision and division of the peritenon, the rupture site could be clearly seen in 17 cases. In 7 cases the rupture site could not be located until after longitudinal incision of the Achilles tendon over a suspected section with palpable softer or firmer parts and in some instances fusiformly thickened. After the rupture site had been located granulation tissue and devitalized tendon tissue was excised. The continuity of the tendon was then restored by various methods: namely end to end suture (8 cases) side-to-side suture (7 cases) suture and plastic repair with a flap (5 cases) and suture and plastic repair with plantaris-longus tendon (4 cases).

Postoperatively the foot plus the lower leg was immobilized in plaster with the foot plantar flexed for 3 weeks. Thereafter the sutures were removed and the patient wore walking plaster for another 3 weeks. Active exercises were started immediately after the operation and were continued after plaster removal until the range of movement in the talocrural joint was normal.

The disability period varied from 1 week to 5 months. It was wholly dependent on the patient's occupation. The majority (18 patients) re-

turned to work within 2 months. The ability to walk on flat ground was recovered within 7 weeks in most and within 2 months in all the cases. All but 2 of the champion athletes resumed full training but these 2 carry on relatively high sports activities as do all the athletes. Half the patients had fully recovered subjectively and objectively within 2 months and all of them had done so within 1 year.

- 1) Reduction of the amount of motor-unit activity in that part of the muscle with ruptured tendon,
- 2) Increased H-reflex response in cases of rupture of the soleus tendon, in other cases normal H-reflexes,
- 3) Shortened contraction time in cases of rupture of the soleus tendon
Increased contraction time and change of the configuration of the contraction curve in cases of rupture of the gastrocnemius tendon

As regards the differential diagnosis, the partial Achilles tendon rupture can be confused with complete rupture tendinitis, peritendinitis, calcaneal bursitis, periostitis, and insufficiency fractures of the fibula or tibia. In most cases the clinical and the electrophysiological examinations will help in differentiating with certainty a partial rupture from the above said conditions.

Out of the 24 patients, the majority (13 patients) had undergone long term (6—18 months) conservative therapy consisting of rest, short wave ultrasonic wave, and X-ray treatment antiphlogistics (Tanderil®, Butazolidin®), local steroid and heparin injections, and immobilization in plaster without any noticeable effect.

The aim of the operative treatment was to restore the muscle-tendon relation so as to re-establish, as near as possible normal function. After exposure of the Achilles tendon with a medial curved incision and division of the peritenon, the rupture site could be clearly seen in 17 cases. In 7 cases the rupture site could not be located until after longitudinal incision of the Achilles tendon over a suspected section with palpable softer or firmer parts and in some instances, fusiformly thickened. After the rupture site had been located, granulation tissue and devitalized tendon tissue was excised. The continuity of the tendon was then restored by various methods: namely end-to-end suture (8 cases), side-to-side suture (7 cases), suture and plastic repair with a flap (5 cases) and suture and plastic repair with plantaris longus tendon (4 cases).

Postoperatively the foot plus the lower leg was immobilized in plaster with the foot plantar flexed for 3 weeks. Thereafter the sutures were removed and the patient wore walking plaster for another 3 weeks. Active exercises were started immediately after the operation and were continued after plaster removal until the range of movement in the talocrural joint was normal.

The disability period varied from 1 week to 5 months. It was wholly dependent on the patient's occupation. The majority (18 patients) re-

Case-histories

Fig 8

Right Achilles tendon The tendon fibres from the medial gastrocnemius belly descending distally follow an increasingly lateral course toward the insertion on the calcaneus where they make up the lateral part of the Achilles tendon. The medial segment of the Achilles tendon is at the insertion made up of tendon fibres from the soleus component. This accounts for the rotation which is characteristic of the course of the Achilles tendon fibres and which has been described by Cummins (1949) and Rosate (1964). Centrally the Achilles tendon is made up mainly of soleus fibres. Ventrally its medial segment is made up of soleus fibres and its lateral segment of fibres from the lateral gastrocnemius. See further the schematic drawings (after Rosate) in the case report.

CASE 2 A 25-year-old policeman and skier who for the last 17 months had had recurrent bursitis impositus of the gastrocnemius and achillotendinitis on the left side

Treatment Rest, an antiphlogistic (Tanderil®) local application of Buta-zolidine ointment five injections of heparin and six of a steroid only two of the latter being given in the Achilles tendon itself and its insertion. The last injection given 3 months before the trauma

Trauma On pressing his right foot down hard for support while grappling with an unruly drunkard he had experienced intense sharp pain in the Achilles tendon of that foot

Subjectively Able to walk but rising on the toes painful

Objectively —3 cm above insertion Achilles tendon thicker ventrally tenderness on palpation and slight depression of tendon contour 10 cm above insertion Marked atrophy and impaired tone of lateral belly of gastrocnemius

X-ray Shadow of calcium deposit immediately above the calcaneus (calcification in haematoma)

Prognosis & E.M.G. Voluntary activity much sparser laterally than medially

Operation (6 weeks after trauma) Transverse and longitudinal rupture of lateral part of tendon from 3 cm to 10 cm above insertion Excision with end-to-end suture (side-to-side)

Histologically Degenerated tendinous tissue without areas of stainable endoplasm Slight ingrowth of granulation tissue Areas of slight perivascular inflammation

Postoperative E.M.G. (3 months) No definite abnormalities

Outpatient check-up (3 months) Using an arch support because of some anterior arch trouble Achilles tendon felt normal Occasionally slight tenderness Operation scar normal Tendon function normal

Return to work 3 months

Operative check-up (7 months) Synovitis due to local overexertion of right knee joint after intensive running exercise Achilles tendon normal

Outpatient check-up (1 year and 7 months) Trochanteric tenobursitis on left side after long-distance running (30 km) Achilles tendon normal on palpation

Results Fully active throughout the racing seasons 1—3 years after operation Belongs to the Stockholm top-class athletes District champion Took part in the Lidnigo race (cross country running 30 km) runs for practice —2½ hours three times a week skis 50 km without any trouble with Achilles tendon

CASE 1 A 21 year old engineer and medium distance runner who before the trauma had had tendinitis of the left Achilles tendon of 3 months duration
Trauma (6 months before operation) At the spurt in a 3000 metre race he felt a snap in the region of the left calf. He rested from training activities for 2 months. On stepping on a threshold he felt the snapping again in the region of the left Achilles tendon.

Treatment Local injection of a steroid just over 2 months after first trauma an antiphlogistic (Tanderil®) and rest no response.

Subjectively (6 months after trauma) No discomfort in daily life the slight test effort to increased activity caused pain and tenderness of Achilles tendon. Training impossible.

Objectively Swelling and tenderness on palpation 5 cm above insertion of tendon. Marked atrophy impaired muscle tone and tenderness on palpation over lateral belly of gastrocnemius.

Preoperative E M G not performed.

Operation (6 months after trauma) Oblique rupture just over 10 cm above insertion through lateral portion of tendon to border of medial part. Granulation tissue found in the gap. Excision with end to end suture.

Histologically Devitalized tendon tissue without areas of stainable endoplasm. Collagen frayed and decolourized. Ingrowth of unspecific granulation tissue.

Return to work 7 weeks.

Postoperative E M G (2½ months) Voluntary activity sparser than normal. No difference between medial and lateral bellies of gastrocnemius.

Outpatient check up (4½ months) Subjectively no great discomfort. He trained 5 times a week running maximally 10 km. Objectively adequate function of tendon.

Postoperative E M G (4½ months) Voluntary activity greatly increased but slight asymmetry between lateral and medial bellies of gastrocnemius.

Outpatient check up (14 months) Subjectively no complaints. Training 6 times a week. Interval — running 200—800 metres. Long distance running maximally 20 km. Objectively operation wound healed normally the atrophy of lateral belly of gastrocnemius barely observable.

Postoperative E M G (14 months) Normal.

Result (4 years after operation) No troubles whatsoever with Achilles tendon. Training regularly 5 times a week for fast and long distance running over 10—70 km.

GL = Gastrocnemius lateralis

GM = Gastrocnemius medialis

S = Soleus

PL = Plantaris longus

CASE 2 A 25 year-old policeman and skier who for the last 17 months had had recurrent bursitis myositis of the gastrocnemius and achillotendinitis on the left side

Treatment Rest an antiphlogistic (Tanderil®) local application of Buta zolidine ointment, five injections of heparin and six of a steroid only two of the latter being given in the Achilles tendon itself and its insertion The last injection given 3 months before the trauma

Trauma On pressing his right foot down hard for support while grappling with an unruly drunkard he had experienced intense sharp pain in the Achilles tendon of that foot

Subjectively Able to walk but rising on the toes painful

Objectively —3 cm above insertion Achilles tendon thicker ventrally tenderness on palpation and slight depression of tendon contour 10 cm above insertion Marked atrophy and impaired tone of lateral belly of gastrocnemius

X-ray Shadow of calcium deposit immediately above the calcaneus (calcification in haematoma)

Prognosis E.M.G. Voluntary activity much sparser laterally than medially

Operation (6 weeks after trauma) Transverse and longitudinal rupture of lateral part of tendon from 3 cm to 10 cm above insertion Excision with end to end suture (side to side)

Histologically Devitalized tendinous tissue without areas of stainable endoplasm Slight ingrowth of granulation tissue Areas of slight periscular inflammation

Postoperative E.M.G. (3 months) No definite abnormalities

Outpatient check up (3 months) Using an arch support because of some anterior arch trouble Achilles tendon felt normal Occasionally slight tenderness Operation scar normal Tendon function normal

Return to work 3 months

Outpatient check up (7 months) Synovitis due to local over exertion of right knee joint after intensive running exercise Achilles tendon normal

Outpatient check up (1 year and 7 months) Trochanteric tenobursitis on left side after long distance running (30 km) Achilles tendon normal on palpation

Results Fully active throughout the racing seasons 1—3 years after operation Belongs to the Stockholm top class athletes District champion Took part in the Lidingö race (cross country running 30 km) runs for practice 2— ½ hours three times a week skis 50 km without any trouble with Achilles tendon

CASE 3 A 46 year old electrician who frequently had to climb ladders
First trauma (1½ years before operation) Sustained a blow of a reinforcing iron bar against right Achilles tendon after which he had troubles in the form of increasing tenderness and thickening over the tendon for 1½ years
Treatment An antiphlogistic (Tanderil®) short wave treatment After local steroid injection within 6 months of the trauma the swelling diminished
Subjectively (1½ years after trauma) Difficulties in rising on his toes and climbing ladders Felt stabbing pain in the tendon on getting on to a chair
Objectively Right Achilles tendon thinner than left one because of depression in tendon contour laterally and above insertion Dorsal extension in talocrural joint increased to 10° more than normal Generalized atrophy of gastrocnemius

Preoperative EMG Volitional activity much less laterally than medially
On the waiting list for operation of lateral partial rupture of Achilles tendon
Second trauma (6 weeks after objective examination and 2 weeks after EMG) Stumbled on a board at building site and felt something like a violent blow from behind

Objectively Complete rupture of tendon with diastasis 4—5 cm above insertion Thompson's test did not elicit plantar flexion of foot

Operation (1½ years after first trauma and on the day after second trauma)
 1) Old rounded off partial rupture of lateral portion of tendon proximal end of rupture retracted just over 5 cm from distal end which was slightly more irregularly rounded 2) Fresh rupture with haemorrhages and torn tendon fibres through medial and soleus portions of tendon Plastic repair by Silfverskiöld's method (modified)

Histologically Devitalized tendon tissue with altered collagen stainability and poorly visible fibrous structure

Postoperative EMG (7 weeks) Sparse volitional activity in bursts mainly medially

Return to work 11 weeks

Outpatient check up (13 weeks) Normal range of movement and tendon function Able to rise on his toes for the first time in just over 1½ years

Postoperative EMG (3½ years) Fully normal

Result (3½ years after operation) Able to climb ladders etc without difficulties no trouble with Achilles tendon

CASE 4 A 29-year-old engineer and ice hockey player with a 3 year history of recurrent tendinitis of left Achilles tendon

Treatment Heparin injection Local steroid injection 4 months and 2 months before trauma led to temporary improvement An antiphlogistic (Tanderil®)

First trauma (7 weeks before operation) During an ice hockey match he pulled up suddenly — to a solid object on the ice — and felt a jarring pain in left Achilles tendon

Subjectively (5 weeks after trauma) Swelling and pain on walking up and down stairs unable to rise on his toes

Objectively Minor defect in tendon contour laterally — 3 cm above insertion with a rounded off thickening distally which was tender to palpation Dorsal extension in talocrural joint increased to a few degrees more than normal

Preoperative EMG Decreased volitional activity laterally

On the day list for operation

Second trauma (8 days after examination) Tripped on stairs and felt a tear in Achilles tendon

Objectively A distinct depression in Achilles tendon laterally 3—4 cm above insertion but tendon intact medially Thompson's test gave plantar flexion

X-ray Soft tissue space around tendon was infiltrated

Operation (7 weeks after first trauma)

- 1 Old rounded off rupture laterally in lateral portion of tendon
- 2 Fresh oblique rupture with haemorrhages in lateral portion of tendon also involving a small part of medial portion

Plastic repair by Silfverskiöld's method (modified)

Histologically Partially devitalized tendon tissue and still vital tendon tissue with altered collagen stainability and frayed fibrous structure In places tendon transformed into granulation tissue with sparse unspecific inflammatory cell infiltration

Return to work Resumed his studies 10 days after operation

Postoperative EMG (4 months) Normal

Outpatient check up (6 months) Some tightness in gliding tissue around Achilles tendon and operation scar for first 4 months after removal of plaster Operation scar normal

Result Fully active at ice hockey every season for 3 years after operation and has suffered no tendon troubles whatsoever

CASE 5 A 42 year old engineer and allround athlete who 1 year before the trauma had been given a local injection of a steroid for tendinitis of the left Achilles tendon after which he had been free from symptoms for 1 year
Trauma (12 months before operation) On sudden start at -20°C in the Vasa Ski Race (85 km) he felt a burning pain in left Achilles tendon Persisting trouble with tendon

Treatment Six heparin and 9 local steroid injections An antiphlogistic (Tanderil®) ultrasonic waves and rest for 2 months had no effects over a period of 11 months

Subjectively (11 months after trauma) Pain in Achilles tendon on movement tendon felt swollen and clotted in the night no trouble in his daily activities

Objectively (11 months after trauma) Thickening about 10 cm above insertion of tendon with tenderness on palpation over this area Atrophy of 15 cm of calf but no difference between lateral and medial bellies of gastrocnemius Slightly increased dorsal extension

Preoperative E M G Voluntary activity fairly good but somewhat less laterally though not sufficiently so to give rise to suspicion of rupture on the basis of E M G

Operation (12 months after trauma) Fusiform thickening 6—7 cm above insertion with a laterally darker tendinous streak one cm in length and adhesions ventrally in this area Exposure revealed a cystic cavity 5 cm long with a few thin ruptured tendon fibres the walls showed partly obliterated tendon structure Excision up to normal tendon tissue side to side suture

Histologically Areas of split devitalized tendon tissue with newly formed tendon like granulation tissue

Outpatient check up (4 weeks) Plaster removed after 4 weeks Operation wound slightly irritated over an area of one cm Catgut suture which had loosened was removed Pain in plantar aponeurosis Arch support for pain in calcaneus spur

Return to work 6 weeks after operation

Outpatients check up (6 weeks) Subjectively no complaints No tenderness on palpation over operating field Operation wound normal

Postoperative E M G (6 weeks) Normal

Outpatient check up (6 months) In full training but after running for about $1\frac{1}{2}$ hours he noticed symptoms of tenobursitis of knee joint but had no troubles whatsoever with Achilles tendon

Outpatient check up (7 months) After cross country running he had stabbing pain in region of right calf small partial rupture of gastrocnemius

Postoperative E M G (7 months) Completely normal

Result (2 years and 9 months) Fully active in skiing and training without any troubles whatsoever

CASE 6 A 9 year old electrician football bandy and ice hockey player with a history of recurrent tendinitis of both Achilles tendons for 3 years. Local steroid injection 1 year before the trauma had relieved the symptoms during the bandy and ice hockey season. As the condition was aggravated after football training practice EMG was performed but showed no definite abnormalities.

Trauma (9 months before operation and 2 weeks after above said EMG)

Stumbled at work and felt a sharp sudden pain in right Achilles tendon.

Treatment Short wave and X ray an antiphlogistic (Tanderil®) Hirudoid and Butazolidine ointment heparin injections local steroid injection enabled the patient to play bandy and ice hockey in the winter but not football.

Subjectively (8 months after trauma) Sharp pain in right Achilles tendon on increased activity. He had to walk with stiff foot.

Objectively Laterally a good 2 cm above insertion a tear was suspected in Achilles tendon contour which proximal to this site was thickened and tender to palpation.

Preoperative EMG Interpretation difficult possibly slightly sparser voluntary activity in the lateral part of the right gastrocnemius.

X ray Right Achilles tendon slightly thickened 5 cm above calcaneus.

Operation (8 months after trauma) Peritenon adherent to subcutis. Laterally 3-5 cm above insertion several small ruptures relatively superficially. Plastic repair with a flap from medial common aponeurosis.

Histologically 1) Peritenon with newly formed granulation tissue of tendon like type. 2) Devitalized tendon tissue and newly formed tendon like granulation tissue.

Return to work months.

Outpatient check up (3½ months) At first some stiffness in the morning. Some tenderness over operation area. Operation wound normal. He had commenced training.

Postoperative EMG (3½ months) No definite pathological changes. No asymmetry.

Results (1 year after operation) Played in a football match 5 months after operation. Had been fully active in football and regained his old swiftness. No troubles with right Achilles tendon but had had an injury of collateral ligament in right knee (ochanter tenobursitis) and partial semimembranosus rupture. Operation wound satisfactory. No tenderness on palpation. Right Achilles tendon slightly thicker than left one. Fully satisfactory muscle tendon function. Normal range of movement in ankle joint.

CASE 5 A 42 year old engineer and allround athlete who 1 year before the trauma had been given a local injection of a steroid for tendinitis of the left Achilles tendon after which he had been free from symptoms for 1 year
Trauma (12 months before operation) On sudden start at -70°C in the Vasa Ski Race (85 km) he felt a burning pain in left Achilles tendon
 Persisting trouble with tendon

Treatment Six heparin and 9 local steroid injections An antiphlogistic (Tanderil®) ultrasonic waves and rest for 2 months had no effects over a period of 11 months

Subjectively (11 months after trauma) Pain in Achilles tendon on movement tendon felt swollen and clotted in the night no trouble in his daily activities

Objectively (11 months after trauma) Thickening about 10 cm above insertion of tendon with tenderness on palpation over this area Atrophy of 1.5 cm of calf but no difference between lateral and medial bellies of gastrocnemius Slightly increased dorsal extension

Preoperative E M G Voluntary activity fairly good but somewhat less laterally though not sufficiently so to give rise to suspicion of rupture on the basis of E M G

Operation (12 months after trauma) Fusiform thickening 6—7 cm above insertion with a laterally darker tendinous streak one cm in length and adhesions ventrally in this area Exposure revealed a cystic cavity 5 cm long with a few thin ruptured tendon fibres the walls showed partly obliterated tendon structure Excision up to normal tendon tissue side to side suture

Histologically Areas of split devitalized tendon tissue with newly formed tendon like granulation tissue

Outpatient check up (4 weeks) Plaster removed after 4 weeks Operation wound slightly irritated over an area of one cm Catgut suture which had loosened was removed Pain in plantar aponeurosis Arch support for pain in calcaneus spur

Return to work 6 weeks after operation

Outpatient check up (6 weeks) Subjectively no complaints No tenderness on palpation over operating field Operation wound normal

Postoperative E M G (6 weeks) Normal

Outpatient check up (6 months) In full training but after running for about $1\frac{1}{2}$ hours he noticed symptoms of tenobursitis of knee joint but had no troubles whatsoever with Achilles tendon

Outpatient check up (7 months) After cross country running he had stabbing pain in region of right calf small partial rupture of gastrocnemius

Postoperative E M G (7 months) Completely normal

Results (7 years and 9 months) Fully active in skiing and training without any troubles whatsoever

CASE 8 A 40 year old electrical fitter and allround athlete

Trauma (14 months before operation) While cycling up a 400-metre long hill standing on the pedals he felt violent pain in right Achilles tendon. Before this incident he had had a period of training running 7400 km and cycling 100 km. After trauma tendon painful for 14 months.

Treatment He arn and steroid injections on 9 occasions. An antiphlogistic (Tanderil®). Immobilization in plaster and 3 weeks of hospital care.

Subjectively Stabbing pain on increased activity but also aching at rest. Acentuated after an effort to run in the Vasa Ski Race after skiing 50 km he was unable to walk.

Objectively Right Achilles tendon twice as thick as left one with fusiform thickening 3—4 cm above insertion: intense tenderness on palpation over this area and possibly slight incongruence of contour medially and dorsally. Dorsal extension in talocrural joint increased to 15° more than normal.

Preoperative EMG No definite abnormalities but slight difference in comparison with EMG 6 weeks previously. Reduced voluntary activity in the medial part of gastrocnemius.

X-ray Right Achilles tendon twice as thick as left one unclearly outlined. Soft tissue infiltration.

Operation (14 months after trauma) Dorsally Achilles tendon furrowed centrally with small haemorrhages and enclosed in hardened callous granular tissue. Dorsal medial partial rupture with rounded off rupture ends. End to end suture and plastic repair with a flap turned over from lateral normal tendon fascicle.

Histologically Partly devitalized tendon tissue with decolourized collagen and haec and the reformation of granulation tissue.

Postoperative EMG (6 weeks) Normal.

Return to work 6 weeks after operation.

Outpatient check up (5 months) He had just completed the Lidingö Race cross country running 50 km without any troubles with Achilles tendon. Operation scar normal. No tenderness on palpation.

Results (12 years after operation) Another Lidingö Race and two Vasa Ski Races after operation. Trained training on hard road the following seasons 1600—1750 km. Employed as a gymnastics master on duty for 7 hours every day. No trouble whatsoever with Achilles tendon.

CASE 7 A 51 year old carpenter and footballer

Trauma (1 year before operation) While kicking a football against a brick wall and joggling he felt intense pain in right Achilles tendon and then had difficulties in walking

Treatment Two local steroid injections 1 week after trauma Rest an anti-phlogistic (Tanderil®) Immobilisation in plaster for 3 weeks Elastic bandage

Subjectively (11 months after trauma) Tenderness and difficulty in walking up and down stairs

Objectively Thickening with fluctuation and tenderness on palpation 3—4 cm above insertion of tendon Muscle atrophy with reduced tone laterally Dorsal extension in ankle joint slightly increased

Preoperative E M G Voluntary activity somewhat less laterally

X ray Achilles tendon slightly thickened over an area about 4 cm in length 2 cm proximal to calcaneus

Operation (1 year after trauma) Fusiform thickening 3—4 cm above insertion of opaque appearance laterally Longitudinal incision in softer part revealed a cystic cavity in lateral portion of tendon with granulation tissue and partly obliterated tendon structure Excision end to end suture

Histologically Devitalized tendon tissue with frayed fibrous structure poor stainability in endoplasmic areas and altered collagen stainability To this tissue attached streaks of newly formed granulation tissue rich in collagen and of finely streaked and wavy structure which differed from that of normal tendon tissue

Outpatient check up (7 months) Occasionally slight pain Operation scar normal Strength in foot and lower leg not quite normal return to work therefore postponed

Outpatient check up (2½ months) Subjectively and objectively virtually free from symptoms

Return to work 2½ months after operation

Postoperative E M G (4½ months) Normal

Result (2 years after operation) Climbs scaffolds Heavy weight bearing on Achilles tendon — wheeling loads of mortar Plays tennis No trouble whatsoever with the tendon

CASE 8 A 40 year old electrical fitter and allround athlete

Trauma (14 months before operation) While cycling up a 400-metre long hill standing on the pedals he felt violent pain in right Achilles tendon. Before this incident he had had a period of training running 400 km and cycling 100 km. After trauma tendon painful for 14 months.

Treatment Heparin and steroid injections on 9 occasions. An antiphlogistic (Tander 13). Immobilization in plaster and 3 weeks of hospital care.

Subjectively Stabbing pain on increased activity but also aching at rest a centimetrel after an effort to run in the Vasa Ski Race after sking 30 km he was unable to walk.

Objectively Right Achilles tendon twice as thick as left one with fusiform thickening, 3—4 cm above insertion intense tenderness on palpation over this area and possibly slight incongruence of contour medially and dorsally. Dorsal extension in talocrural joint increased to 15° more than normal.

Properly *EMG* No definite abnormalities but slight difference in comparison with *EMG* 6 weeks previously. Reduced voluntary activity in the medial part of gastrocnemius.

X-ray Right Achilles tendon twice as thick as left one, unclearly outlined, soft tissue infiltration.

Operation (14 months after trauma) Dorsally Achilles tendon furrowed centrally with small haemorrhages and enclosed in hardened callous granulation tissue. Dorsomedial partial rupture with rounded off rupture ends. End to end suture and plastic repair with a flap turned over from lateral normal tendon fascicle.

Histologically Partly de-talized tendon tissue with decolourized collagen and here and there formation of granulation tissue.

Postoperative *EMG* (6 weeks) Normal.

Return to work 6 weeks after operation.

Outpatient check up (5 months) He had just completed the Lidings Race cross country running 30 km without any troubles with Achilles tendon. Operation scar normal. No tenderness on palpation.

Results (12 years after operation) Another Lidings Race and two Vasa Ski Race. He operation T ended running on hard road the following seasons 1600—1750 km. Employed as a gymnastics master on duty for 7 hours every day. No trouble whatsoever with Achilles tendon.

CASE 7 A 51 year old carpenter and footballer

Trauma (1 year before operation) While kicking a football against a brick wall and juggling he felt intense pain in right Achilles tendon and then had difficulties in walking

Treatment Two local steroid injections 1 week after trauma Rest an anti phlogistic (Tanderil®) Immobilisation in plaster for 3 weeks Elastic bandage

Subjectively (11 months after trauma) Tenderness and difficulty in walking up and down stairs

Objectively Thickening with fluctuation and tenderness on palpation 3—4 cm above insertion of tendon Muscle atrophy with reduced tone laterally Dorsal extension in ankle joint slightly increased

Preoperative E M G Voluntary activity somewhat less laterally

X ray Achilles tendon slightly thickened over an area about 4 cm in length 2 cm proximal to calcaneus

Operation (1 year after trauma) Fusiform thickening 3—4 cm above insertion of opaque appearance laterally Longitudinal incision in softer part revealed a cystic cavity in lateral portion of tendon with granulation tissue and partly obliterated tendon structure Excision end to end suture

Histologically Devitalized tendon tissue with frayed fibrous structure poor stainability in endoplasmic areas and altered collagen stainability To this tissue attached streaks of newly formed granulation tissue rich in collagen and of finely streaked and wavy structure which differed from that of normal tendon tissue

Outpatient check up (2 months) Occasionally slight pain Operation scar normal Strength in foot and lower leg not quite normal return to work therefore postponed

Outpatient check up (2½ months) Subjectively and objectively virtually free from symptoms

Return to work 3½ months after operation

Postoperative E M G (4½ months) Normal

Result (2 years after operation) Climbs scaffolds Heavy weight bearing on Achilles tendon — wheeling loads of mortar Plays tennis No trouble whatsoever with the tendon

CASE 19 A 65 year-old colonel and athlete who had had medial tendinitis of left Achilles tendon for 4 months. E.M.G. negative. After local steroid injection medially only about 3—4 cm above insertion he had been symptom free until injury occurred.

Trauma Stepping side ways on his foot he slipped on the kerb and felt stabbing pain in the calf.

Subjectively (3 days after trauma) Unable to rise on the toes because of pain.

Objectively Tenderness on palpation and oedema about 10 cm above insertion. A dent in tendon contour laterally. Dorsal extension in talocrural joint increased to 5—10° more than normal.

Proper use E.M.G. Volitional activity much less in left than in right gastrocnemius muscle. Asymmetry with fewer motor units laterally than medially. Prolonged contraction time.

X-ray Left Achilles tendon thickened.

Operation (2 weeks after trauma) Haemorrhages and partial rupture laterally 10 cm above insertion. Rupture involved greater part of lateral tendon fascicle with diastasis of 3—4 cm between rupture ends distally ensheathed by tendinous callus. Excision and end-to-end suture. Medially tendon structure fully normal.

Histologically Devitalized tendon tissue showing altered collagen stainability and frayed fibrous structure. Slight tendency to formation of granulation tissue. Signs of fibrin exudation around areas of devitalized tendon tissue.

Outpatient check up (2 months and 10 days after operation) Subjectively usually symptom free. Operation scar normal.

Return to work 50% 2 months after operation.

Outpatient check up (5 months) A tender part laterally 15—20 cm above insertion had troubled him for a month but had cleared up at time of examination. Operation scar normal. No tenderness on palpation. Normal range of movement in ankle joint.

Return to full work 5 months after operation.

Postoperative E.M.G. (5 months) Fully normal.

Results (2 years after operation) Walked fast every day for 1½—2 hours without stopping. Half running occasionally. Light physical exercises. No trouble with Achilles tendon after operation.

- CASE 9** A 54 year old woman engineer and athlete who had been operated on for subcutaneous complete rupture of left Achilles tendon in 1946
- Trauma** During a cross country run she slipped on a stone and felt a sharp pain in right Achilles tendon
- Treatment** Rest
- Subjectively** Weight bearing painful difficulty in walking up and down stairs Stabbing pain on increased activity Aching at rest
- Objectively** (1 months after trauma) Diffuse thickening of Achilles tendon 3—4 cm above insertion and tenderness on palpation of this area as well as slightly further proximally After increased weight bearing by walking up and down a flight of stairs the tenderness was localized distinctly laterally
- Preoperative E M G** Fairly good voluntary activity slightly reduced laterally Shape of contraction curve deviated from normal slightly prolonged duration Pathological finding not wholly characteristic but suspected to be evidence of rupture
- Operation** (1 month after trauma) Achilles tendon seemed to be intact but a longitudinal incision over an area of opaque appearance revealed a cystic cavity with haemorrhages and two torn tendon ends united by granulation tissue Excision up to healthy tendon tissue resulting in a cavity 10—12 cm long Side to side suture
- Histologically** Partially devitalized tendon tissue with poorly stainable endoplasm areas and reduced collagen stainability Granulation tissue formed in places Minimal inflammatory cell infiltration The continuity of collagen fibres here and there broken by granulation tissue which indicated the presence of partial rupture
- Outpatient check up** (2 months) Subjectively no complaints Operation scar normal No tenderness on palpation
- Postoperative E M G** (2 months) Normal
- Return to work** Just over 7 months after operation
- Result** During the first 2 postoperative years she was able to carry on various forms of sports downhill skiing physical exercises twice a week with ½ hour of cross country running each time No trouble whatsoever with Achilles tendon

CASE 10 A 65 year-old colonel and athlete who had had medial tendinitis of left Achilles tendon for 4 months. E.M.G. negative. After local steroid injection medially only about 3—4 cm above insertion he had been symptom free until injury occurred.

Trauma: Stepping sideways on his foot he slipped on the kerb and felt stabbing pain in the calf.

Subjectively (3 days after trauma) Unable to rise on the toes because of pain.

Objectively Tenderness on palpation and oedema about 10 cm above insertion and dent in tendon contour laterally. Dorsal extension in talocrural joint increased to 5—10° more than normal.

Preoperative E.M.G. Volitional activity much less in left than in right gastrocnemius muscle. Asymmetry with fewer motor units laterally than medially. Prolonged contraction time.

X-ray Left Achilles tendon thickened.

Operation (2 weeks after trauma) Haemorrhages and partial rupture laterally 10 cm above insertion. Rupture in olef greater part of lateral tendon fascicle with diastasis of 3—4 cm between rupture ends distally ensheathed by tendinous callus. Excision, end to end suture. Medially tendon structure fully normal.

Histologically Devitalized tendon tissue showing altered collagen stability and frayed fibrous structure. Slight tendency to formation of granulation tissue. Signs of fibrin exudation around areas of devitalized tendon tissue.

Operative check up (2 months and 10 days after operation) Subjectively usually symptom free. Operation scar normal.

Return to work 50% 2 months after operation.

Operative check up (5 months) Anterior part laterally 15—20 cm above insertion had troubled him for a month but had cleared up at time of examination. Operation scar normal. No tenderness on palpation. Normal range of movement in ankle joint.

Return to full time work 5 months after operation.

Postoperative E.M.G. (5 months) Fully normal.

Results (1 year after operation) Walked fast every day for 1½—2 hours without stopping. Half running occasionally. Light physical exercises. No trouble with Achilles tendon after operation.

CASE 11 A 44 year old district manager and allround athlete who had had recurrent tendinitis of left Achilles tendon for just over 1 year Seven months after onset he had been given a local steroid injection the symptoms had disappeared after 1 week and he had then been symptom free for 6 weeks up to the time of the trauma

First trauma (3 months before operation) Distortion of right ankle joint with excessive weight bearing on left Achilles tendon

Treatment Local steroid injection plus an antiphlogistic (Tanderil®) produced no effect

EMG (6 weeks after trauma) No abnormalities

Second trauma (7 weeks before operation) Tripped and made a false step on kerb felt a violent pain in left Achilles tendon and calf muscle

EMG No abnormalities

Treatment An antiphlogistic (Tanderil®) plus local steroid injection but only in medial gastrocnemius part which was tender on palpation (tennis leg) tenderness over this region disappeared but pain in Achilles tendon persisted

Subjectively (1 months before operation) Tenderness over lower part of tendon Incessant pain on walking Unable to run more than 50 metres

Objectively Soft tissue swelling tenderness on palpation over tendon and suggested fluctuation medially 5—6 cm above insertion Atrophy and reduced tone of medial gastrocnemius belly Slightly increased dorsal extension in talocrural joint

X ray Left Achilles tendon thicker than right one Probably partial rupture

Preoperative EMG Slightly reduced voluntary activity in the medial gastrocnemius belly

Operation (3 months after first trauma) Medially an area of just over 10 cm of Achilles tendon covered with hardened tissue Exposure revealed three partly oblique tears in medial portion of tendon Excision suture plus plastic repair using a flap from lateral portion

Histologically 1) Highly sclerosed tendon like granulation tissue Slight inflammatory cell infiltration Centrally yellowish red collagen bundles being rests of old tendon tissue with vascularization 2) Same as above Profuse vascularization Lymphomonocytic infiltrates around vessels Areas of transition from granulation tissue to newly formed tendon like connective tissue

Return to work 4 weeks

Outpatient check up (4 months) After walking for 30—45 minutes he had still some pain on medial side adhesions? Normal range of movement in talocrural joint Can rise on his toes without pain No tenderness on palpation

Postoperative EMG (4 months) Normal

Outpatient check up (10 months) Started training about 7 months after operation Competing in orienteering contests almost every other day and never over distances shorter than 7 km Subjectively no complaints Very occasionally slight pricking but rapidly passing sensation in Achilles tendon

Results (2 years) Subjectively and objectively wholly symptom free as regards Achilles tendon Operation scar normal No muscle atrophy Some complaints of pain on movement in right shoulder and elbow when playing tennis

CASE 1 A 47 year old manager former speedway driver and athlete

Trauma (5 months before operation) Caught his left foot under a stone and was butted on the calf by a vicious ram. He felt a violent pain above the ankle as if something had been broken. Interpreted as a muscle sprain.

Treatment Elastic bandage rest

Subjectively (3 months after trauma) Pain above left ankle. Difficulty in walking up and down a flight of stairs. Cannot stand on tiptoes.

Objectively Depress on in Achilles tendon contour with palpable diastasis 4 cm in length in lateral part of tendon. Medially tendon appeared to be at least partially intact at palpation. Atrophy of lateral and medial gastrocnemius. Dorsal extension in talocrural joint increased to 15° more than normal. Thompson's test gave plantar flexion of foot though with reduced muscular strength.

X-ray Left Achilles tendon much thicker than right one. Infiltration in fat in front of Achilles tendon.

Prognosis EMG Greatly reduced volitional activity laterally possibly also in the soleus.

Operation (5 months after trauma) Hardened tissue enclosed a partial rupture which involved lateral as well as soleus portions and also part of medial tendon fascicle. Centrally a plantaris longus tendon as thick as tip of little finger. So as to achieve satisfactory opposition at suturing the intact medial fascicle was also divided. Plastic repair using plantaris tendon and turning down of a flap from medial fascicle.

Histologically Partially devitalized tendon tissue changing into granulation and newly formed collagen poorer tendon like tissue. Fairly dense lymphocytic infiltrates surrounded the vessels. The surface of some areas was covered with fibrin fragments.

Output at check up (3 months) Subjectively relatively normal. Operation was normal. Relatively slight tenderness on palpation over site of repair. Normal range of movement in ankle joint.

Return to work 3½ months after operation.

Postoperative EMG planned but not performed until 2 years after operation as the time did not suit the patient and the foot did not trouble him at all.

EMG (2 years) Completely normal.

Results (1 year) 100% recovery. Fully active cycling, skiing and swimming without any trouble whatsoever with Achilles tendon.

CASE 11 A 44 year old district manager and allround athlete who had had recurrent tendinitis of left Achilles tendon for just over 1 year Seven months after onset he had been given a local steroid injection the symptoms had disappeared after 1 week and he had then been symptom free for 6 weeks up to the time of the trauma

First trauma (3 months before operation) Distortion of right ankle joint with excessive weight bearing on left Achilles tendon

Treatment Local steroid injection plus an antiphlogistic (Tanderil®) produced no effect

E M G (6 weeks after trauma) No abnormalities

Second trauma (7 weeks before operation) Tripped and made a false step on kerb felt a violent pain in left Achilles tendon and calf muscle

E M G No abnormalities

Treatment An antiphlogistic (Tanderil®) plus local steroid injection but only in medial gastrocnemius part which was tender on palpation (tennis leg) tenderness over the region disappeared but pain in Achilles tendon persisted

Subjectively (1 months before operation) Tenderness over lower part of tendon In essant pain on walking Unable to run more than 50 metres

Objectively Soft tissue swelling tenderness on palpation over tendon and suggested fluctuation medially 5—6 cm above insertion Atrophy and reduced tone of medial gastrocnemius belly Slightly increased dorsal extension in talocrural joint

X ray Left Achilles tendon thicker than right one Probably partial rupture

Preoperative E M G Slightly reduced voluntary activity in the medial gastrocnemius belly

Operation (3 months after first trauma) Medially an area of just over 10 cm of Achilles tendon covered with hardened tissue Exposure revealed three partly oblique tears in medial portion of tendon Excision suture plus plastic repair using a flap from lateral portion

Histologically 1) Highly sclerosed tendon like granulation tissue Slight inflammatory cell infiltration Centrally yellowish red collagen bundles being rests of old tendon tissue with vascularization 2) Same as above Profuse vascularization Lymphomonocytic infiltrates around vessels Areas of transition from granulation tissue to newly formed tendon like connective tissue

Return to work 4 weeks

Outpatient check up (4 months) After walking for 30—45 minutes he had still some pain on medial side adhesions? Normal range of movement in talocrural joint Can rise on his toes without pain No tenderness on palpation

Postoperative E M G (4 months) Normal

Outpatient check up (10 months) Started training about 7 months after operation Competing in orienteering contests almost every other day and never over distances shorter than 7 km Subjectively no complaints Very occasionally slight prickling but rapidly passing sensation in Achilles tendon

Result (2 years) Subjectively and objectively wholly symptom free as regards Achilles tendon Operation satisfactory No muscle atrophy Some complaints of pain on movement in right shoulder and elbow when playing tennis

CASE 1 A 47 year old manager former speedway driver and athlete

Trauma (5 months before operation) Caught his left foot under a stone and was butted on the calf by a vicious ram. He felt a violent pain above the ankle as if something had been broken. Interpreted as a muscle sprain.

Treatment Elastic bandage rest

Subjectively (5 months after trauma) Pain above left ankle. Difficulty in walking up and down a flight of stairs. Cannot stand on tiptoes.

Objectively Depression in Achilles tendon contour with palpable diastasis 4 cm in length in lateral part of tendon. Medially tendon appeared to be at least partially intact at palpation. Atrophy of lateral and medial gastrocnemius. Dorsal extension in talocrural joint increased to 15° more than normal. Thompson's test gave plantar flexion of foot though with reduced muscular strength.

X-ray Left Achilles tendon much thicker than right one. Infiltration in fat in front of Achilles tendon.

Prognosis E.A.G. Greatly reduced volitional activity laterally possibly also in the soleus.

Operation (5 months after trauma) Hardened tissue enclosed a partial rupture which involved lateral as well as soleus portions and also part of medial tendon fascicle. Centrally a plantaris longus tendon as thick as tip of little finger. So as to achieve satisfactory opposition at suturing the intact medial fascicle was also divided. Plastic repair using plantaris tendon and turning down of a flap from medial fascicle.

Histologically Partially devascularized tendon tissue changing into granulation and newly formed collagen poorer tendon like tissue. Fairly dense lymphocytic infiltrates surrounded the vessels. The surface of some areas was covered with fibrin fragments.

Outpatient check up (3 months) Subjectively relatively normal. Operation scar normal. Relatively slight tenderness on palpation over site of repair. Normal range of movement in ankle joint.

Return to work 3½ months after operation.

Postoperative EMG planned but not performed until 7 years after operation, as the time did not suit the patient and the foot did not trouble him at all.

EMG (7 years) Completely normal.

Result (7 years) 100% recovery. Fully active cycling, skiing and swimming without any trouble whatsoever with Achilles tendon.

CASE 11 A 44 year old district manager and allround athlete who had had recurrent tendinitis of left Achilles tendon for just over 1 year Seven months after onset he had been given a local steroid injection the symptoms had disappeared after 1 week and he had then been symptom free for 6 weeks up to the time of the trauma

First trauma (4 months before operation) Distortion of right ankle joint with excessive weight bearing on left Achilles tendon

Treatment Local steroid injection plus an antiphlogistic (Tanderil®) produced no effect

EMG (6 weeks after trauma) No abnormalities

Second trauma (7 weeks before operation) Tripped and made a false step on kerb felt a violent pain in left Achilles tendon and calf muscle

EMG No abnormalities

Treatment An antiphlogistic (Tanderil®) plus local steroid injection but only in medial gastrocnemius part which was tender on palpation (tennis leg) tenderness over this region disappeared but pain in Achilles tendon persisted

Subjectively (1 months before operation) Tenderness over lower part of tendon Incessant pain on walking Unable to run more than 50 metres

Objectively Soft tissue swelling tenderness on palpation over tendon and suggested fluctuation medially 5—6 cm above insertion Atrophy and reduced tone of medial gastrocnemius belly Slightly increased dorsal extension in talocrural joint

X-ray Left Achilles tendon thicker than right one Probably partial rupture *Preoperative EMG* Slightly reduced voluntary activity in the medial gastrocnemius belly

Operation (3 months after first trauma) Medially an area of just over 10 cm of Achilles tendon covered with hardened tissue Exposure revealed three partly oblique tears in medial portion of tendon Excision suture plus plastic repair using a flap from lateral portion

Histologically 1) Highly sclerosed tendon like granulation tissue Slight inflammatory cell infiltration Centrally yellowish red collagen bundles being rests of old tendon tissue with vascularization 2) Same as above Profuse vascularization Lymphomonocytic infiltrates around vessels Areas of transition from granulation tissue to newly formed tendon like connective tissue

Return to work 4 weeks

Outpatient check up (4 months) After walking for 30—45 minutes he had still some pain on medial side adhesions? Normal range of movement in talocrural joint Can rise on his toes without pain No tenderness on palpation

Postoperative EMG (4 months) Normal

Outpatient check up (10 months) Started training about 7 months after operation Competing in orienteering contests almost every other day and never over distances shorter than 7 km Subjectively no complaints Very occasionally slight pricking but rapidly passing sensation in Achilles tendon

Result (2 years) Subjectively and objectively wholly symptom free as regards Achilles tendon Operation scar normal No muscle atrophy Some complaints of pain on movement in right shoulder and elbow when playing tennis

CASE 14 A 4 year old university student and champion long-distance runner. He had had trouble with left Achilles tendon for $1\frac{1}{2}$ years clinically diagnosed as achillotenobursitis. Local steroid injection in the calcaneal bursa relieved the symptoms and enabled him to run races until he sustained the injury.

History ($1\frac{1}{2}$ years before operation) When training barefooted on a golf course he felt a sudden pain in the region of left Achilles tendon immediately above insertion. The pain persisted.

Treatment Rest Butazolidine ointment. After 5 months a steroid injection was given locally at the calcaneal insertion and after another $\frac{1}{2}$ months into the region of the bursa. As no response was noted dimethyl sulphoxide (DMSO) was tried.

Subjectively (1 month before operation) Pain and tenderness on increased activity. Almost unable to run 50 metres to catch a bus.

Objectively Achilles tendon distinctly thicker immediately above insertion and tender to palpation laterally. Atrophy of just over 1 cm of triceps surae.

Preoperative E.M.G. Volitional activity reduced laterally.

X-ray Left Achilles tendon twice as thick as right one.

Operation ($1\frac{1}{2}$ years after trauma) Achilles tendon looked normal on the whole but 3—4 cm above insertion there was a slightly uneven and raised section. Incision revealed a cystic cavity with two rupture ends and profuse granulation tissue and fibrin. End to end suture.

Histologically Degenerated tendon tissue partly transformed into and infiltrated by unspecific granulation tissue with newly formed tendon like connective tissue. Some areas were coated with a fibrin like mass.

Return to work 10 days after operation.

Outpatient check up (3 months) Subjectively no complaints. Operations as normal. Full range of movement in talocrural joint.

Postoperative E.M.G. ($3\frac{1}{2}$ months) Normal.

Result (years) No troubles with Achilles tendon. Training twice a week running 7—8 km. He had not resumed competitive sports because of studies among other reasons.

CASE 13 A 38 year old engineer and handball player

Trauma During a handball game he experienced violent pain in left Achilles tendon. Believed that somebody had kicked him, fell down on the floor.

Treatment Elastic bandage for 3 weeks, plaster for 3 weeks.

Subjectively (6 weeks after trauma) Pain in calf on ordinary walking, had to walk with stiff foot.

Objectively Marked swelling of lower part of leg and ankle. Achilles tendon greatly thickened and tender to palpation both medially and laterally, a little further than 10 cm above insertion. Depression in tendon contour. Dorsal extension in ankle increased to a few degrees more than normal. Subtotal rupture? Thompson's test gave plantar flexion though with reduced strength.

Preoperative E M G Voluntary activity less than normal, mainly medially. When medial needle was pushed deeper — into soleus — definite asymmetry was no longer noted. Probably partial rupture, most likely medially. Neurophysiologically complete rupture unlikely, as for instance the asymmetry of Hoffmann's reflex seen in complete ruptures was absent. X-ray Achilles tendon could not be defined and thus not assessed.

Operation (2½ months after trauma) Hardened and greatly thickened peritendon haemorrhage. Underneath the peritendon another layer of hardened tissue at first interpreted as being Achilles tendon. Longitudinal incision in this tissue exposed normal tendon tissue and the site of rupture, which involved both medial and lateral portion of Achilles tendon 3–4 cm above insertion. Soleus portion intact. As excision of all devitalized tendon and granulation tissue left a considerable defect, it was necessary to divide the soleus tendon and let the two parts overlap slightly so as to ensure satisfactory opposition at suturing, which thus became step-like. A minor defect laterally was covered with a flap from the exposed aponeurosis. It was considered doubtful whether the final result would be as good as those obtained earlier by operation of Achilles tendon rupture.

Histologically Devitalized tendon tissue and highly sclerosed granulation tissue of tendon-like appearance. Inflammatory cell infiltration around the vessels.

Outpatient check up (3 months) Seroma or bursa-like collection developed in the postoperative course and had to be punctured several times. Operation scar normal. Otherwise no troubles with Achilles tendon.

Return to work 3 months after operation.

Postoperative E M G (1½ months) Fully normal.

Outpatient check up (1 year and 4 months) He had been skiing in the winter and then trained running without any great discomfort. Objectively a fusiform thickening with slight fluctuation was palpated dorsally over Achilles tendon 1½–9½ cm above insertion. Operation scar normal, no adhesions. No tenderness on palpation over Achilles tendon. Atrophy of 1 cm of the calf.

Results (1 year and 10 months after operation) Full training, no discomfort.

CASE 14 A 24 year old university student and champion long-distance runner. He had had trouble with left Achilles tendon for 1½ years clinically diagnosed as achillobursitis. Local steroid injection in the calcaneal bursa relieved the symptoms and enabled him to run races until he sustained the injury.

Trauma (1½ years before operation) When training barefooted on a golf course he felt a sudden pain in the region of left Achilles tendon immediately above insertion. The pain persisted.

Treatment Rest. Butazolidine ointment. After 5 months a steroid injection was given locally at the calcaneal insertion and after another 2½ months into the region of the bursa. As no response was noted dimethyl sulphoxide (DMSO) was tried.

Subjectively (1 month before operation) Pain and tenderness on increased activity. Almost unable to run 50 metres to catch a bus.

Objectively Achilles tendon distinctly thicker immediately above insertion and tender to palpation laterally. Atrophy of just under 1 cm of triceps surae.

Preoperative EMG Volitional activity reduced laterally.

X-ray Left Achilles tendon twice as thick as right one.

Operation (1½ years after trauma) Achilles tendon looked normal on the whole but 3–4 cm above insertion there was a slightly uneven and raised section. Incision revealed a cystic cavity with two rupture ends and profuse granulation tissue and fibrin. End to end suture.

Histologically Devitalized tendon tissue partly transformed into and infiltrated by unspecific granulation tissue with newly formed tendinous connective tissue. Some areas were coated with a fibrin like mass.

Return to work 10 days after operation.

Outpatient check up (3 months) Subjectively no complaints. Operations as normal. Full range of movement in talocrural joint.

Postoperative EMG (3½ months) Normal.

Result (2 years) No troubles with Achilles tendon. Training twice a week running 7–8 km. He had not resumed competitive sports because of studies among other reasons.

CASE 13 A 38 year old engineer and handball player

Trauma During a handball game he experienced violent pain in left Achilles tendon. Believed that somebody had kicked him, fell down on the floor.

Treatment Elastic bandage for 3 weeks, plaster for 3 weeks.

Subjective's (6 weeks after trauma) Pain in calf on ordinary walking, had to walk with stiff foot.

Objectively Marked swelling of lower part of leg and ankle. Achilles tendon greatly thickened and tender to palpation both medially and laterally, a little further than 10 cm above insertion. Depression in tendon contour. Dorsal extension in ankle increased to a few degrees more than normal. Subtotal rupture? Thompson's test gave plantar flexion though with reduced strength.

Preoperative E.M.G. Voluntary activity less than normal, mainly medially. When medial needle was pushed deeper — into soleus — definite asymmetry was no longer noted. Probably partial rupture, most likely medially. Neurophysiologically complete rupture unlikely, as for instance the asymmetry of Hoffmann's reflex seen in complete ruptures was absent.

X-ray Achilles tendon could not be defined and thus not assessed.

Operation (2½ months after trauma) Hardened and greatly thickened peritenon, haemorrhages. Underneath the peritenon another layer of hardened tissue at first interpreted as being Achilles tendon. Longitudinal incision in this tissue exposed normal tendon tissue and the site of rupture, which involved both medial and lateral portion of Achilles tendon 3—4 cm above insertion. Soleus portion intact. As excision of all devitalized tendon and granulation tissue left a considerable defect, it was necessary to divide the soleus tendon and let the two parts overlap slightly so as to ensure satisfactory opposition at suturing, which thus became step-like. A minor defect laterally was covered with a flap from the exposed aponeurosis. It was considered doubtful whether the final result would be as good as those obtained earlier by operation of Achilles tendon rupture.

Histologically Devitalized tendon tissue and highly sclerosed granulation tissue of tendon-like appearance. Inflammatory cell infiltration around the vessels.

Outpatient check up (3 months) Seroma or bursa-like collection developed in the postoperative course and had to be punctured several times. Operation scar normal. Otherwise no troubles with Achilles tendon.

Return to work 3 months after operation.

Postoperative E.M.G. (6½ months) Fully normal.

Outpatient check up (1 year and 4 months) He had been skiing in the winter and then trained running without any great discomfort. Objectively a fusiform thickening with slight fluctuation was palpated dorsally over Achilles tendon 7½—9½ cm above insertion. Operation scar normal, no adhesions. No tenderness on palpation over Achilles tendon. Atrophy of 1 cm of the calf.

Result (1 year and 10 months after operation) Full training, no discomfort.

CASE 16 A 63 year old foreman and gymnast

First trauma During gymnastic exercise practice he felt a snap in right Achilles tendon, after which the tendon was painful on movement and tender

Treatment Local steroid injection on five occasions as from 10th day after trauma

Second trauma (2 months after first one) On running out of the way of a car he felt as though someone had kicked him on the calf 15 cm above insertion of Achilles tendon

Subjectively Pain on movement swelling of tendon A feeling of weakness on plantar flexion of foot

Objectively Defect in medial contour of tendon 7 cm above insertion Tendon felt thinner than normal on palpation Atrophy and reduced tone of medial gastrocnemius belly Dorsal extension in talocrural joint increased to 5—10 more than normal

Preoperative EMG Volitional activity much less medially than laterally

X-ray Infiltration of the fat at lower portion of tendon probably due to partial rupture

Operation (3½ months after first trauma) Transverse rupture of medial portion of tendon about 7 cm above insertion a layer of hardened tissue found over the site End to end suture

Histologically Partially devascularized tendon tissue showing transformation into sclerosed granulation tissue which in parts resembled tendon tissue Here and there lymphomonocytic cell infiltration

Return to work 3 months after operation

Postoperative EMG (3½ months) Volitional activity symmetric Normal contraction time Hoffmann's reflexes normal

Outpatient check up (1 year and 2 months) Achilles tendon still slightly stiff but otherwise no discomfort Operation scar normal Normal strength in foot and calf muscles though still suggested atrophy of gastrocnemius bellies but normal tone Range of movement in right talocrural joint same as in left one

Result (2 years) Subjectively no trouble with Achilles tendon Taking daily walks sking 20 km or so without any discomfort

CASE 15 A 22 year old buyer and champion hurdler with a 1 month history of tendinitis of right Achilles tendon the condition was relieved by rest
Trauma (10 months before operation) During a cross country run he trod on a stone with accompanying hyperextension of right ankle Felt as if something had been torn in the Achilles tendon

Treatment Relative rest for just over 3 months DMsO was tried by produced no effect

EMG (3 months after trauma) Slight reduction of volitional activity tendon probably not ruptured One local steroid injection cleared the condition for 3 months but the sharp pain returned on increased weight bearing Complete rest for a further 2 months

Subjectively (10 months after trauma) Pain and tenderness over Achilles tendon on eversion and stepping side ways on the foot No discomfort at work

Objectively Right Achilles tendon increased in width fusiform thickening and tenderness on palpation laterally about 5 cm above insertion Atrophy of lateral gastrocnemius belly Dorsal extension in talocrural joint increased to 5—10° more than normal

Preoperative EMG Asymmetry of volitional activity which was reduced laterally prolonged contraction time and altered shape of contraction curve Minor lateral rupture

X ray Right Achilles tendon much thicker than normal above insertion Oedema in front of insertion

Operation (10 months after trauma) Rupture of the whole soleus portion and small part of lateral portion of tendon about 1 cm above insertion End to end suture after mobilization and shortening of unruptured part of tendon

Histologically Old devitalized tendon tissue and sclerosed granulation tissue resembling normal tendon tissue but having more irregular collagen structure Moderate lymphomonocytic cell infiltration around the vessels

Return to work 3 weeks after operation wearing walking plaster

Outpatient check up (13 months) No trouble with Achilles tendon at sprint rushes badminton and physical exercises Able to run distances of 5 km for 2—3 consecutive days without any discomfort but after that time Achilles tendon increasingly tender

Objectively Operation scar normal Tendon contour slightly irregular Slight tenderness on palpation immediately above insertion No measurable muscle atrophy

Postoperative EMG Normal

Result (2 years) No trouble at all with Achilles tendon No tenderness after long distance running

CASE 18 A 27 year old farmer and Swedish champion in 10 000 metres
Trauma (5 days before operation) At the end of a 10 000 metre race in an international competition at a height of 2000 metres in Turkey possibly stepping sideways on the raised edge of the track he felt sharp stabbing pain in left Achilles tendon and fell down on the track

Objectively (within a minute of trauma) Distinct tenderness on palpation medially over Achilles tendon maximal tenderness at calcaneal insertion and junction between soleus muscle and free portion of tendon

Preoperative E.M.G. Reduced volitional activity in medial gastrocnemius belly Asymmetry still more marked when the needle was pushed deeper Hoffmann's reflex slightly increased

Operation (5 days after trauma) Haemorrhages beneath peritenon Medial rupture 5-6 cm above insertion involving about $\frac{1}{4}$ of the cross section of the medial portion of tendon at the border of the soleus muscle Resection of ruptured ends of tendon and suture with grafting plantaris-longus tendon in the resulting tendon defect

Histologically Devitalized tendon tissue with altered collagen stainability and non stainable endoplasm areas Virtually no granulation tissue Slight fibrin exudation

Return to work 3 months after operation

Outpatients check up (7½ months after operation): Resumed training barely 3 months after operation running 8 km 4-5 times a week, occasionally 17 km The main reason for his visit was pain on lateral aspect of left knee **Diagnosis** Tenobursitis No trouble at all with Achilles tendon operation scar normal On palpation Achilles tendon felt slightly thickened over the part into which plantaris tendon was grafted No tenderness on palpation Atrophy of calf over 1 cm but muscle tone normal Normal range of movement in ankle joint

Postoperative E.M.G. Fully normal

Results (1 year and 7 months) Completed racing season 1 year after operation without any discomfort Still among topperformers running 10000 metres in 30 minutes and 20 seconds in a competition for the Swedish Champion ship although he did not win it No trouble at all with Achilles tendon

CASE 17 A 47 year old engineer and allround athlete

Trauma (10 years before operation) After betting he went untrained for a 1500 metre run and felt intense pain in left Achilles tendon Since then he had two — three spells of recurring trouble every year in the form of tingling pain

Treatment Rest during the most troublesome periods otherwise no special treatment no steroids

Subjectively (2 months before operation) After skating without sustaining any particular injury he noticed swelling in the region of Achilles tendon and had pain even at rest stiffness in the morning

Objectively Left Achilles tendon much broader and thicker than normal tendon contour bulged dorsally just above insertion extending proximally as far as 5 cm below gastrocnemius Tenderness on palpation most marked laterally

Preoperative E M G Distinct decrease of volitional activity laterally

X ray Left Achilles tendon markedly thickened Soft tissues infiltrated

Operation (10 years after the suspected trauma) Several yellow soft areas of granulation tissue interspersed with tendon like hardened tissue Diffuse ill defined infiltration Excision of the soft granulation areas and the hardened tendon like tissue revealed a section extending obliquely laterally medially suspected to represent the original site of rupture Side to side suture Diameter of Achilles tendon shortened by just over one third It was considered doubtful whether normal postoperative tendon function would be achieved

Histologically Partial devitalization with hyalinization of collagen and fraying of fibrin structure Profuse formation of fresh and old granulation tissue showing also myxomatous degeneration Foreign body reaction seen in the areas Sparse unspecific inflammatory cell infiltration

Return to work 4 weeks after operation

Outpatient check up (6 weeks) Operation scar normal Foot easily raised to mid position No tenderness on palpation

Postoperative E M G (1 ½ years) Normal

Result (1 year and 7 months) No trouble at all with Achilles tendon 100 % recovery Full training for last 10 months running distances of 7—8 km without discomfort

CASE 20 A 43 year-old bank official and orienteer with a history of tendinitis of left Achilles tendon for 10 months no known injury Had to give up racing

Treatment Rest Butazolidine ointment no steroid injection

Subjectively Pain in left Achilles tendon on movement Unable to run for more than 1/2 hour Tendon painful even on quick walking Discomfort in the morning

Objectively Achilles tendon slightly increased in width Distinct tenderness on palpation 3-4 cm above insertion, most markedly laterally Atrophy of calf over 1 cm

Preoperative E M G Volitional activity reduced laterally

X ray Left Achilles tendon slightly thicker in upper part

Operation A section of tendon laterally 5-6 cm above insertion, slightly thicker and softer than normal Longitudinal incision At a depth of 3-4 mm an oedematous area in which two normal tendon streaks disappeared into tissue of opaque appearance — granulation tissue Excision side to side suture

Histologically Devascularized tendon tissue and mostly newly formed granulation tissue with finely streaked wavy collagen structure not resembling normal tendon tissue Some areas of inflammatory infiltration peritendinously

Return to work 2 months after operation

Postoperative E M G (5 months) Volitional activity increased but still slightly less than normal, not asymmetric Further regression

Outpatient check up (5 months) Tenderness over Achilles tendon persisted longer than usual Commenced training but suffered some pain on the following day Operation scar normal

Results (1 year and 6 months) No trouble at all with Achilles tendon Went for orienteering runs every Sunday and on skis without discomfort

CASE 19 A 28 year old engineer and cross country runner who had a history of tendinitis of right Achilles tendon for 2 years After local steroid injections he was symptom free for 7 and 3 months respectively until he sustained the injury

Trauma (1 year before operation) During a cross country run he tripped over root of tree placing excessive weight on right Achilles tendon and felt sharp pain in tendon

Treatment Rest DMSO and one local steroid injection produced no effect Partial rupture suspected

EMG (2 months after trauma) No abnormalities

EMG (5 months after trauma) No abnormalities

Subjectively (9 months after trauma) Had to give up training tried skiing but tendon too painful Complained of pain on ordinary walking and walking up and down stairs

Objectively Thickening and possibly slight irregularity of tendon contour distinct tenderness on palpation 3 cm above insertion of tendon most marked medially Reduced tone laterally atrophy of calf over 1 cm

Preoperative EMG Reduced voluntary activity in soleus and Hoffmann's reflex heightened (150 % of that on left side) central rupture

X ray Right Achilles tendon thickened and poorly outlined soft tissue infiltration Minor areas of calcification in anterior part of tendon

Operation (1 year after trauma) Achilles tendon looked intact but on palpation thickened at the level of lowermost part of soleus Incision revealed central rupture with sanguinolent fluid haemorrhages and several rupture ends with areas of calcification Excision side to side suture

Histologically Devitalized tendon tissue with obliterated fibrous structure poorly stainable endoplasm and altered collagen stainability Tendon like granulation tissue partly with marked inflammatory changes

Return to work 6 weeks after operation

Outpatient check up (2 months) Subjectively relatively little discomfort walked without difficulty Operation scar normal No tenderness on palpation Triceps surae function normal Able to rise on his toes

Postoperative EMG (3 months) Symmetric and normal volitional activity Hoffmann's reflex and contraction time normal

Result (1 year and 5 months) Commenced training 3 months after operation As he lives in Africa no final check up has been made but according to information the condition has healed up completely

CASE 7 A 7 year-old student of technology and international sprinter who had had tendinitis of right Achilles tendon 4½ months before the operation. After local steroid injection he had been completely free from symptoms during a period of hard training.

Trauma (3½ months before operation) On making a vigorous push off at the start of a 100 metre race he felt an intense jarring pain in the right Achilles tendon. No discomfort in daily life but avoided rising on his toes. Training impossible.

Objectively Irregular tendon contour medially. Muscle atrophy and reduced tone in medial gastrocnemius belly. Increased dorsal extension in ankle joint.

X-ray Slightly thickened tendon with oedema towards the fatty space.

EMG Reduced voluntary activity medially.

Operation Medially two rounded-off rupture ends enclosed by granulation tissue. Plastic repair using the plantaris longus tendon.

Histologically Devitalized tendon tissue with a few necrotic areas (suggested calcification). Tophus like sparse granulation tissue.

Return to work 1 week.

Postoperative EMG (3 months) Normal.

Postoperative EMG (8 months) Normal.

Outpatient check up (8 months) Gradually increased training. Able to do high jumping of 1.8 metres but some diffuse pain on sprint training.

Outpatient check up (13 months) Probably started too hard training in interval as well as long distance running. Had developed diffuse pain further laterally which gave rise to suspicion of imminent lateral rupture. Operation scar normal but Achilles tendon felt slightly indurated and had not resumed its normal soft elastic consistence. EMG was still wholly normal.

Result (15 months) He had completed another period of hard training and was free of all symptoms. Training 3—4 days a week long-distance running over 8—9 km and interval running over 6 times 1000 metres or 300 metres at relatively high tempo. No trouble at all with Achilles tendon.

CASE 21 A 45 year old taxi driver and amateur athlete who for 7 months had had trouble with his left Achilles tendon following a road race After local steroid injection on two occasions he had no trouble for 2 months until the injury occurred

First trauma (3½ months before operation) On kicking a ball he felt a snap in his left calf medially Partial rupture was suspected but EMG showed no definite abnormalities

Second trauma (2 days before operation) During a 400 metre run he felt violent sharp pain and an audible snapping in the region of left Achilles tendon He completed the race and was then admitted to Serafimerlasarettet

Objectively Transverse indentation in tendon contour and marked tenderness on palpation over tendon 3—4 cm above insertion Haematoma Thompson's test gave normal plantar flexion but with slightly reduced strength

Preoperative EMG Volitional activity greatly reduced in lateral and medial gastrocnemius bellies No definite asymmetry No difference in contraction time between the two legs but downward deflection of curve markedly prolonged on left side

Conclusion Partial rupture soleus portion should be intact

X ray Achilles tendon thickened locally its anterior portion poorly outlined against the fatty space

Operation (2 days after trauma) Bleeding under peritenon towards gastrocnemius bellies Transverse rupture through medial and lateral parts of tendon 4—5 cm above insertion but soleus portion intact End to end suture The soleus tendon which was too long after resection of the two rupture ends was sutured both to the medial and to the lateral side of the already sutured rupture ends

Histologically Streaks of devitalized tendon tissue Sclerosed tendon like granulation tissue predominated Both old and fresh haemorrhages Sparse fresh granulation tissue around haemorrhages and vessels Minimal inflammatory cell infiltration

Return to work 2 months after operation

Postoperative EMG (4 months) Normal

Outpatient check up (9 months) No complaints whatsoever Trained and competed in track and field athletics without any trouble with Achilles tendon Had noticed slight thickening of tendon contour about 10 cm above insertion but no tenderness on palpation peritenon possibly slightly thickened in this area Operation scar normal

Result (1 year and 3 months) No complaints Recommended full training and competing

CASE 4 A 19 year old office clerk and medium distance runner

Tram (8 months before operation) On running indoors on a hard wooden floor he felt sharp pain in right Achilles tendon

Treatment After steroid injection medially at insertion of tendon the tenderness over this area disappeared. The troubles returned when he commenced training.

Subjectively Stabbing pain in Achilles tendon on attempts at training and on walking up and down a flight of stairs

Objectively Slight swelling of peritendon, fairly intensive tenderness on palpation from insertion of tendon for just over 6 cm in proximal direction. Uncertain whether pain was localised more laterally or more medially. On palpation of relaxed tendon the point of maximal tenderness was laterally 6-7 cm above insertion. Slight atrophy of lateral gastrocnemius belly.

Positive EMG (on two occasions) Some decrease of volitional activity in lateral gastrocnemius belly. Hoffmann's reflex heightened. Shortened contraction time. Deformed contraction curve.

X-ray Right Achilles tendon somewhat thickened.

Operation Dorsally. Achilles tendon normal. Ventrally indurated section at junction between soleus muscle and lateral portion of tendon. Removal of granulation tissue revealed a rupture of ventral portion of tendon 5 cm in length and extending slightly obliquely. End-to-end (side to side) suture.

Histologically Partially devitalised tendon tissue with altered collagen stainability and poor stainability in endoplasmic areas. Narrow streaks of newly formed granulation tissue rich in collagen and of tendon-like structure. Very sparse monocyctic infiltration around some small vessels.

Return to work 7 weeks.

Postoperative EMG (3 months) Normal. Only slight asymmetry of volitional activity medially laterally.

Outpatient check up (3 months) No trouble with Achilles tendon, apart from sensation of cramp in calf muscles on riding a bicycle ergometer. Operation scar normal. No tenderness on palpation. Gradually increased training.

Results (1 year and 1 month) Able to run maximum 20 km without any trouble with Achilles tendon for the first 8-9 months after operation. Then he fell ill with pleurisy. Strength of leg and tendon returned after disk bar training.

S

P.L.

G.L.

CASE 23 A 23 year old gymnastics master and medium distance runner with a 7 month history of tendinitis of right Achilles tendon at insertion laterally

After local steroid injection he was symptom free for 3 months

Trauma (3 months before operation) Sharp pain medially in Achilles tendon after training Persistent pricking pain probably due to pressure of shoe stiffener while running in training shoes with built up heels

EMG No abnormalities

Treatment Rest from training

Subjectively (1 month before operation) On attempts at training he suffered pain sometimes so sharp that he could hardly walk

Objectively Tendon contour irregular medially a few cm above insertion tenderness on palpation over this area

Preoperative EMG Volitional activity reduced medially Medial rupture suspected

X ray Dorsal border of fatty space in front of Achilles tendon somewhat indistinctly outlined

Operation A thick tendon like thread extended medially from Achilles tendon a good 5 cm above insertion obliquely into the thickened wall of the bursa to which it adhered Partial medial longitudinal rupture Excision side to side suture

Histologically Coarse bundled connective tissue rich in collagen only slightly resembling devitalized tendon tissue and granulation tissue highly sclerosed and transformed into tendon like tissue

Return to work 6 weeks

Outpatient check up (7 months) Unable to commence training for the first few postoperative months but had cycled instead Laterally above insertion slight thickening which was tender to palpation — peritenon? It had virtually disappeared at the time of examination Lately he had trained at irregular intervals Operation scar normal

Result (13 months) Training 4 times a week running 10—15 km No trouble with the right Achilles tendon but some discomfort from the left one

Introduction

At the end of last century arthrodesis was introduced as an operative technique for various disabilities and lesions of the hip. Since then, however, the attitude towards and the indications for this method have varied. It is now accepted in orthopaedic surgery and has become one of the classical treatments. Many problems are involved in the use of this technique and therefore extensive research work, especially clinical, has been carried out.

The operation is of a major kind and for a long time implicated primary mortality at a rate which could not be disregarded. The improved technique of anaesthesia and the control of fluid balance have almost eliminated these risks. Longstanding immobilization is necessary to achieve fusion. This results in a high frequency of post-operative complications such as thromboses, embolism, stiffness of the knee joint, respiratory and urinary tract infections and so on. To shorten the time of immobilization, numerous methods of internal fixation have been suggested. The aim has been to make the primary fixation of the joint components stable enough to allow the patient to get out of bed early and also to avoid plaster immobilization of other joints.

The proposed methods of osteosynthesis have been elaborated clinically. The efficiency of these methods have been reported as part of all the factors which are involved in the clinical healing results.

In this study an attempt is made to explain theoretically and experimentally the conditions of osteosynthesis in arthrodesis of the hip. Furthermore, experiments were carried out to establish the effectiveness of different methods in achieving primary stability. For this purpose a suitable technique was elaborated.

PART I

Historical Review

The surgical procedure *arthrodesis* carried out to prevent mobility of a joint by fusion, was denominated by Eduard Albert in 1877. In 1878 he performed this operation in a knee joint and in 1892 in a hip joint. At that time however several other authors had described the operation in the hip. Heusner (1884) and Lampugnani (1885) had performed operations on a few cases of congenital dislocation. Lagrange (1886), Dollinger (1891) and Dargaignez (1891) described operative techniques using different kinds of internal fixation. In 1892 von Winawater also applied arthrodesis of the hip.

Besides Albert Albee contributed at an early stage by introducing arthrodesis of the hip. His first case reported in 1908 was very successful. The indication was osteoarthritis and the arthrodesis was performed by using an intra articular technique adductor tenotomy and fixation with a larger plaster hip spica. Five weeks later the plaster was removed up above the knee and after nine weeks the patient was mobilized. After four months he was back working as a patrol man.

An important indication at this time was the various types of infection in the hip especially tuberculous arthritis. The aim was if possible to avoid engaging the actual joint in the operation. In 1913 Maragliano and Albee performed the first extra articular arthrodeses with bone grafting. The graft was applied in an ilio femoral position. Various positions of the graft were described during the 1920's by a number of surgeons. Maragliano (1919) described a technique of ischio-femoral bone grafting as well as Trumble (1931). Brittain (1932) developed this technique to the so called ilio femoral V arthrodesis.

During the 1930's attention was again directed to a combination of the different techniques of arthrodesis with internal fixation.

Van Nes (1932), Burns (1935, 1939) and Watson Jones (1934, 1938) emphasized the importance of stable immobilization to obtain a successful result. The immobilization was not considered satisfactory unless internal fixation completed the plaster spica. The technique of osteosynthesis re-

Besides the general complications as a consequence of the operation the difficulty is associated with ensuring successful union. In so-called fibrous healing some authors have reported good clinical results (Charnley 1953, Mortens 1960, Morris 1966). As opposed to bone union pain was however not always abolished. Die Arthrodesis kann natürlich nur zur Schmerzfreiheit führen wenn eine vollkommene ossäre Ankylos eintritt (Schindler 1958).

The high frequency of non union as reported by some authors (inter alia Stinchfield, Cavallaro 1950, Cholmeley 1956, Lipscomb and Mac Caslin 1961, Williams 1962) accounts for the hesitation in adopting this technique.

Attempts have been made to improve the union by large and well fitting contact surfaces, bone grafting by improved methods of fixation, subtrochanteric osteotomy and longstanding immobilization in plaster.

The surgeon's aim is to bring about a union in the best functional position with the shortest possible bedrest.

Important factors of the operative technique are

- I Position of Arthrodesis
- II Contact Surfaces and Bone Grafting
- III Technique of Internal Fixation
- IV Subtrochanteric Osteotomy in Arthrodesis

commended by these authors, and gradually coming into usage was fixation with a three-flanged nail

Some methods elaborated during the last decades include derangement of the joint. This was done by resection of the caput, dislocation of the caput through the acetabulum (either by fracturing the acetabulum or reshaping the caput and dislocating it into a bore in the acetabulum) or by pelvic osteotomy with dislocation (Charnley, 1953; Kuntscher, 1953, 1956; Muller, 1953; Dwyer, 1961)

Arthrodesis was during the last two to three decades challenged by competitive methods, such as different types of arthroplasty and osteotomy. At the end of the 1930s it was believed that one plastic operation was carried out in ten arthrodesis, while twenty years later plastic operations and arthrodesis were performed in a ratio of two to one (Friberg, 1958). At present the reverse seems to prevail as compared to the 1930s. Many authors advocate the great advantages of arthrodesis. Albee (1921) thus writes: 'There is hardly any operation that gives a larger percentage of very grateful and satisfied patients than the arthrodesis.' Watson Jones (1956) maintains: 'No operation is more advantageous to the patient, more satisfactory to the surgeon, more reliable for restoration of the function.' Blount (1956) says: 'Arthrodesis of the hip is one of the most valuable procedures for the relief of disease pain or disability of the hip.' Crawford-Adams (1966) points out the advantages of arthrodesis.

Its reliability in abolishing pain, the stability it affords, its capacity to stand up to hard work and its permanence. Hobler (1964) believes: 'Die Arthrodesis schafft ein stabiles Bein, führt zu Schmerzfreiheit, bürgt für ein relativ gutes Gangbild und ist unabhängig vom Muskelgleichgewicht.' He also quotes Creyssels: 'Bedauert man manchmal eine Arthroplastik gemacht zu haben, so bedauert man selten den Endschluss zur Arthrodesis gefasst zu haben.'

The main disadvantage of arthrodesis of the hip is the actual object of the operation, namely the loss of mobility in the joint. The motor function of the body changes, the gait may be affected and it may be difficult to carry out certain movements, especially the lumbar spine will be subjected to further tension. If ankylosis can be achieved in a functional position which is the most suitable for the individual, the restrictions will be reduced. It is also noteworthy that the indications for the operation are generally based upon severely restricted movements of the joint connected with pain. The pain is often associated with muscular contractures which are believed to result also in restricted lumbar mobility. With abolishing pain the patient often gets a paradoxical sensation of a greater range of movement.

I Position of Arthrodesis

In the literature published during the last three decades, the authors seem to agree upon the recommended positions. The usually recommended position is flexion at 20—30 degrees, neutral position between abduction and adduction, and outward rotation at 0—10 degrees (Table I). The lack of a well defined initial position from which the angles are measured is remarkable however.

Usually, the desired flexion is achieved by using the technique recommended by Burns and Watson-Jones. The patient is lying on his back with his leg in contact with the table. The lordosis of the lumbar spine is then supposed to correspond to a flexion in the hip of 20—30 degrees. Lindahl (1966) measured the angle between the normal leg at maximum extension and the leg to be arthrodesed. The angle between the legs should then be about 45 degrees. Together with Ahlback (1966) Lindahl also described a roentgenological measuring technique.

In the frontal plane the position should be neutral. Abduction is recommended when leg shortening has to be compensated. Lindstrom (1956) however warned against compensating shortening through abduction as the gait will deteriorate. Konforti (1962) claimed that an abduction position will cause increased back pain.

Several authors point out the difficulty in measuring the angle for abduction/adduction. Furthermore, the neutral position gives an angle between the longitudinal axis of the femur and the vertical plane at 5—10 degrees in a standing position (Weinreich 1959, Herbert 1960, Crawford Adams 1966).

Adams (1931) adopted Kingsley's and Lovett's methods from 1888 for measuring flexion and abduction. Dickson (1951) designed a so called coxometer in order to facilitate angle measuring in both the sagittal and the frontal planes. Lindahl (1965) introduced a technique for determining the abduction by measuring the distance between the medial malleoli with the legs together. A difference of 1 cm means an abduction of approximately 3 degrees.

The adduction position ought to be avoided due to the risk of disturbed balance and gait. Herbert (1960) however stated that an adduction of 10 degrees would be suitable and Alvik (1962) suggests 2—5 degrees. The

II Contact Surfaces and Bone Grafting

1 Intra articular Contact

The first arthrodeses were performed as intra articular procedures Albee (1908) used a chisel to plane the upper part of the caput so that this would fit against an equally planed acetabulum. By dislocation of the joint and removal of the cartilage from the joint surfaces attempts were made to improve the contact surfaces. Watson Jones (1938) recommends this technique combined with internal fixation. Attitudes towards dislocation of the joint vary. The critics especially Charnley (1953) maintain that the contact surface actually becomes smaller by the caput being reduced relative to the acetabulum. According to his technique the caput/collum are converted into a cylindrical or cone-shaped plug which will fit in a drilled bore through the acetabulum into the pelvis. Dickson (1947) tries to avoid reducing the caput in relation to the acetabulum by laminating the cartilage so that the surfaces will remain congruous. Another method is to adjust the cavity in the acetabulum according to the size of the caput by using a suitable milling tool. Smith and Baab (1949) recommended dislocation in order to remove the cartilage entirely. At the same time they drilled several bores in the caput to facilitate the healing. Vogl (1950) described a method where the caput is not dislocated. Instead he used a chisel through the collum/caput chipping the joint surfaces. Schindler (1958) dislocated the caput and inserted an ilio femoral bone graft. A similar procedure is recommended by Tsoukas (1964).

The advantage of completely removing the articular cartilage is that a large bone contact is obtained. The disadvantage is that the operation will be more extensive, that the nutrition of the caput will be jeopardized by the dislocation and that the position of the joint adjusted prior to operation may not be maintained. Lange (1958) believed that dislocation of the caput will not improve healing but instead increase the risk of non union. Lindstrom (1956), Hobler (1964) and Chapchal (1965) amongst others do not believe in a better result if the joint is dislocated. The operation becomes more extensive and the nutrition of the caput will be impaired. In connection with internal fixation Chapchal also believes that the ligament and the capsule will offer resistance when the nail is hammered into the acetabulum. Verheugen & Navarre (1964) reported non union in 10 per

initial position from which these degrees were measured has not been specified Merle d Aubigne (1963) defined the neutral position thus The line transversing the centre of the femoral head and the centre of the medial condyle of the femur should be perpendicular to the line through the acetabulae He believed that a slight adduction will not cause any disturbance while abduction causes limping compensatory scoliosis and back pain

For the rotation, zero position or slight outward rotation is recommended Charnley (1953) warned against inward rotation as it will then be impossible to take a normal step

In order to get a suitable position from the point of rotation, it is recommended that the patella should be directed upwards when the patient lies on the operating table

II Contact Surfaces and Bone Grafting

1 Intra articular Contact

The first arthrodeses were performed as intra articular procedures Albee (1908) used a chisel to plane the upper part of the caput so that this would fit against an equally planed acetabulum By dislocation of the joint and removal of the cartilage from the joint surfaces attempts were made to improve the contact surfaces Watson Jones (1938) recommends this technique, combined with internal fixation Attitudes towards dislocation of the joint vary The critics especially Charnley (1953) maintain that the contact surface actually becomes smaller by the caput being reduced relative to the acetabulum According to his technique the caput/collum are converted into a cylindrical or cone shaped plug which will fit in a drilled bore through the acetabulum into the pelvis Dickson (1947) tries to avoid reducing the caput in relation to the acetabulum by laminating the cartilage so that the surfaces will remain congruous Another method is to adjust the cavity in the acetabulum according to the size of the caput by using a suitable milling tool Smith and Baab (1949) recommended dislocation in order to remove the cartilage entirely At the same time they drilled several bores in the caput to facilitate the healing Vogl (1950) described a method where the caput is not dislocated Instead he used a chisel through the collum/caput chipping the joint surfaces Schindler (1958) dislocated the caput and inserted an ilio-femoral bone graft A similar procedure is recommended by Tsoukas (1964)

The advantage of completely removing the articular cartilage is that a large bone contact is obtained The disadvantage is that the operation will be more extensive that the nutrition of the caput will be jeopardized by the dislocation and that the position of the joint adjusted prior to operation may not be maintained Lange (1958) believed that dislocation of the caput will not improve healing but instead increase the risk of non union Lindstrom (1956) Hobler (1964) and Chapchal (1965) amongst others do not believe in a better result if the joint is dislocated The operation becomes more extensive and the nutrition of the caput will be impaired In connection with internal fixation Chapchal also believes that the ligament and the capsule will offer resistance when the nail is hammered into the acetabulum Verheugen & Navarre (1964) reported non union in 10 per

cent of their cases of intraarticular arthrodesis with luxation of the joint and 15 per cent without dislocation

2 Bone Grafting

Since Marigliano and Albee in 1913 performed their first cases of bone grafting, the development of this technique became of current interest. The use of bone grafting was to obtain a bridge between the pelvis and the femur, to stimulate the bone regeneration and achieve stabilization. The bone grafting also enabled bridged healing without engaging the actual joint. This was considered advantageous when infections occurred in the joint especially tuberculosis, which at that time was a usual indication for arthrodesis of the hip.

There are several ways of classifying the methods of grafting. The easiest way is to classify according to the positions of the graft, a) the ilio femoral and b) the ischio femoral bone grafting.

a) Ilio-femoral Bone Grafting

The ilio-femoral bone graft can be placed in an extra articular, a para-articular or an intra articular position. The extra articular technique is recommended by Albee (1919), Hibbs (1926), Key (1926), Wilson (1927), Schumm (1929), Girard (1935). Para articular bone grafting has been described by Nove-Josserand (1921), Hass (1922), Mathieu (1926), Albee (1929), Sorell (1930), Henderson (1933), Harris (1935), Kellogg Speed (1937), amongst others.

This procedure has also aroused much interest amongst several authors during latter decades. Thus Davis (1954) used a crista graft with the muscular insertion intact, to ensure blood supply. The graft is placed in a groove across the joint after removal of the articular cartilage. Decoult (1965) modified this technique. He did not dislocate the joint and performed subtrochanteric osteotomy. Cattaneo (1959) used a graft from the greater trochanter and displaced it into the ilium completing with a trans articular graft from the tibia. His experimental investigations revealed that the tibial graft is the strongest, the femoral on the other hand is superior to a graft from the fibula.

Schindler (1958) described a technique resembling that of Hibbs. After removing the articular cartilage a graft of about 12 cm is taken from the lateral side of the greater trochanter and the femoral shaft. It is rotated 180 degrees around its upper end and is fixed to the ilium. He believed that the graft will offer complete stability. Boytchev (1960) drilled a tunnel penetrating the greater trochanter and part of the ilium. Through this tunnel he hammered a suitable bone graft taken from the tibia. Boos (1963)

chiselled off the upper parts of the greater trochanter and the femoral head superseding these by a processed bone Hens ge (1967) also used a processed bone which is inserted as a 13 mm coarse bar into a drilled bore trans articulatingly via the neck and the head

The procedure nowadays in general use is to place a graft from the ilium across the upper part of the joint possibly combined with removal of the articular cartilage and internal fixation (Ghormley 1931 Watson Jones 1938 Lange 1951 Lindstrom 1956)

b) *Ischio femoral Bone Grafting*

De Beule (1909) was the first to describe ischio femoral arthrodesis He resected the head and part of the neck and after medial displacement of the femoral end towards the ischium he used a screw for fixation He did not use any graft Maragliano (1919) published an ischio femoral bone grafting technique Trumble (1931) used a graft which was placed in a rectangular opening cut in the posterior subtrochanteric part of the femur and continuing into a cleft made in the ischium Other authors connected with this technique are Galland (1931) Calve (1932) and Gutierrez (1935) As a rule the graft was taken from the tibia or the fibula Kirsch (1939) however used the 10th rib as a graft

Brittain (1942) developed the ischio-femoral technique into his standard method He emphasized that in arthrodesis the leg tended to become adducted during healing due to the strength of the adductors By placing the graft in an ischio femoral position it will be subject to compression as opposed to a graft in an ilio femoral position which will be subject to tension From the mechanical and healing points of view he preferred the ischio femoral position Later he combined the operation with subtrochanteric osteotomy and internal fixation with a nail Through the osteotomy the graft is placed into the ischium The technique has varied with respect to grafting osteotomy and internal fixation Howard (1950) considered that a long period of plaster immobilization was unnecessary and that the patient could walk with crutches after a few weeks time In his series of 17 he reported 14 cases of ankylosis King (1952) stabilized the osteotomy with a plate to avoid plaster Resina (1954) turned the graft 90 degrees on its side His aim was to achieve a greater stability of the osteotomy This does not coincide with Brittain's idea He claimed that the osteotomy should not be fixed but remain unstable to reduce the stress which otherwise would occur in the arthrodesis because of the long lever formed by the femur

Crawford Adams (1966) gave a survey of the results of various ischio femoral procedures In 7 series reported independently totalling 115 cases

cent of their cases of intraarticular arthrodesis with luxation of the joint and 15 per cent without dislocation

2 Bone Grafting

Since Maragliano and Albee in 1913 performed their first cases of bone grafting, the development of this technique became of current interest. The use of bone grafting was to obtain a bridge between the pelvis and the femur, to stimulate the bone regeneration and achieve stabilization. The bone grafting also enabled bridged healing without engaging the actual joint. This was considered advantageous when infections occurred in the joint, especially tuberculosis, which at that time was a usual indication for arthrodesis of the hip.

There are several ways of classifying the methods of grafting. The easiest way is to classify according to the positions of the graft, a) the ilio-femoral and b) the ischio-femoral bone grafting.

a) *Ilio femoral Bone Grafting*

The ilio femoral bone graft can be placed in an extra articular, a para articular or an intra articular position. The extra articular technique is recommended by Albee (1919), Hibbs (1926), Key (1926), Wilson (1927), Schumm (1929), Girard (1935). Para articular bone grafting has been described by Nove-Jossier and (1921), Hass (1922), Mathieu (1926), Albee (1929), Sorell (1930), Henderson (1933), Harris (1935), Kellogg Speed (1937), amongst others.

This procedure has also aroused much interest amongst several authors during latter decades. Thus, Davis (1954) used a crista graft with the muscular insertion intact to ensure blood supply. The graft is placed in a groove across the joint after removal of the articular cartilage. Decouly (1965) modified this technique. He did not dislocate the joint and performed *subtrochanteric osteotomy*. Cattaneo (1959) used a graft from the greater trochanter and displaced it into the ilium completing with a trans-articular graft from the tibia. His experimental investigations revealed that the tibial graft is the strongest, the femoral on the other hand is superior to a graft from the fibula.

Schindler (1958) described a technique resembling that of Hibbs. After removing the articular cartilage a graft of about 12 cm is taken from the lateral side of the greater trochanter and the femoral shaft. It is rotated 180 degrees around its upper end and is fixed to the ilium. He believed that the graft will offer complete stability. Boytchev (1960) drilled a tunnel penetrating the greater trochanter and part of the ilium. Through this tunnel he hammered a suitable bone graft taken from the tibia. Boos (1963)

III Techniques of Internal Fixation

Already when the first reports were published on arthrodesis of the hip the authors were aware of the fact that stabilization was of importance for the union. The best healing conditions were created by eliminating the movement between the surfaces which were to be joined. During the first decades of the 20th century this was attempted by using a full length hip spica. At the end of the 19th century different types of internal fixation had been tried; however Lagrange (1886) used two carpenter nails. Dollinger (1891) described one method with bolt reinforcement and another with a silver thread stretched between a plate on the inside of the pelvis and a plate on the greater trochanter. In the same year Roersch and Deraigne independently suggested fixation by the use of an ivory pin.

The great problem was to obtain non corrosive osteosynthetic material at this time. This reduced the interest for internal fixation. Not until the 1930s did the question arise again about improving the primary stability by internal fixation.

1 Fixation with Three Flanged Nail

Van Nes (1932) used a thin nail for the osteosynthesis. He was dissatisfied with the stability and therefore tried two crossed nails. Finally he changed over to a three flanged nail of a larger dimension than the usual Smith Petersen nail. Watson Jones (1934) pointed out that the bad results with failures up to 50 per cent were caused entirely by inadequate immobilization. In a series of 16 cases he had inserted a three-flanged nail through the joint, all of which fused. He compared this with the fixation in femoral neck fractures and emphasized the importance of counteracting rotation. In his report Burns (1938) mentioned that in 1935 he began to use a coarse three flanged nail. He agreed that the bad union depended on the inadequate fixation. To begin with he used a three flanged nail of 20 mm diameter but experienced that in many cases it split the trochanteric region. Consequently he changed over to using a nail of the Watson Jones type with a diameter of 15 mm slightly coarser than the Smith Petersen nail (13 mm).

The three-flanged nail has since predominated. This method has been discussed by many authors mainly from the following points of view.

operated according to Trumble, there was a mean healing of 81 per cent. 11 series including 260 cases, operated according to Brittain without internal fixation, show the same rate of fusion. 5 series, 278 cases, operated with V-arthrodesis (ischio femoral graft + nail fixation) fused in 84 per cent. In Crawford-Adams' opinion the disadvantage with Trumble's and Brittain's methods is the long period of immobilization in plaster. On the other hand, Brittain's technique of subtrochanteric osteotomy offers the possibility of correcting a malposition and of eliminating the long lever of the leg. Anyhow, there is a risk of pseudarthrosis in the osteotomy. Mayer (1948) warned against lesions of the sciatic nerve. In his experience it is unadvisable to take the graft from the tibia because of the high rate of post-operative fractures. He recommended that the graft instead should be taken from the ilium. An additional problem is the limited mobility of the knee joint caused by long-term immobilization in plaster. Vesley (1961) kept the plaster on for six months. In his series of 44 cases no patient above 20 years of age regained full mobility of the knee-joint.

Finally, combinations of ilio femoral and ischio femoral grafting are reported (cf. Lapras, 1965). Greenberg (1952) inserted grafts through drilled tunnels into the ischium as well as the ilium and through the joint.

normal procedure in arthrodesis of the hip para articular grafting fixation with a three flanged nail followed by immobilization for three or four months. The nail should be directed towards the deflection point of the ileo-pectineal line and the tip of the nail penetrate the internal cortex. Mayr (1953) stated the same direction in his series of 200 cases. Viernstein (1956) held forth that merely a three flanged nail will not offer satisfactory fixation without immobilization in plaster. His series included 326 operated cases.

Among the authors who during the 1960's discussed the problem of the position of the nail and its stabilizing ability Herbert (1960) suggested that it ought to be directed backwards upwards through the collum towards the lower part of the sacro iliac joint. Sicard & Gerhard (1960) instead placed the nail in the longitudinal axis of the neck if possible slightly backwards. Thompson (1961) pointed out that when the nail is placed centrally it will not have a safe grip in the pelvis. In order to obtain this it must be directed backwards. If at the same time the nail is in the centre of the collum it means that the arthrodesis must be carried out with inward rotation. He mentioned that Wright for that reason used a curved Smith-Petersen nail. Castaing (1962) showed pictures of a centrally positioned nail. Graham (1963) tried to direct the nail backwards and penetrated the internal cortex at the ilio-pectineal line by a more ventral insertion in the femur. Gardiner (1962) preferred a depth in the acetabulum of $2\frac{1}{2}$ cm with the nail through the weight bearing area of the femoral head. Kempf et al (1964) attempted a more vertical direction of the nail so as to prevent flexion-extension. A Bohler nail was used at a depth in the acetabulum of 3-4 cm. Tsoukas et al (1964) also employed a Bohler nail. They kept their patients immobilized in plaster for three months. Cauchoux et al (1965) also advised a coarser nail but later changed over to fixation with two screws. Dickson & Hartman (1965) used a technique which on the whole corresponds to that of Watson Jones. The patients were mobilized 4-6 weeks after the operation but plaster was not always applied. On the other hand the patients must use crutches up to six months. The rate of non union in the follow up was barely 12 per cent.

Crawford Adams (1966) inserted the nail about 2 cm below the greater trochanter and directed it towards the centre of the iliac fossa with an inclination forwards at about 15 degrees. The tip of the nail will then emerge at the arcuate margin of the pelvis. Charnley (1953) and St. Clair Strange (1965) emphasized the anatomical fact that an angle in the transverse plane is formed by the neck of the femur and the body of the ilium. This means that the nail in order to reach deeper into the ilium must be inclined backwards.

- a) Technique (position of nail ability to stabilize, plaster immobilization)
- b) Complications

a *Technique*

Watson-Jones (1938) described the technique he used for arthrodesis of the hip and advised that the nail should penetrate 2.5 cm into the acetabular roof and that the immobilization in plaster should be maintained for 2½ months. In 1956, he stated that the position of the nail should be oblique in the collum. In his series of 120 cases 94 per cent healed. Haggart (1945) reported a series operated according to Watson-Jones technique. He pointed out that the nail prevents adduction and rotation but not completely, flexion-extension.

Burns (1939) indicated an inclined direction of the nail through the collum in the frontal plane. He mentioned that roentgenologically, an antero-posterior view will not reveal if the nail is safely secured in the pelvis. The tip of the nail may seem to lie in the bone while in reality it lies inside the true pelvis. Thompson (1961) also remarked on this phenomenon. In order to avoid an erroneous position of the nail, Burns recommended that a special oblique view should be taken as well.

Bailey & Jackson Burrows (1939) advised a steeper direction of the nail than for fractures of the collum. The insertion should be made further down in the femoral shaft, about 1.25 cm behind the anterior surface of the femur. The nail will then perforate the upper area of the caput. The operation includes drilling of several bores through the head to achieve a more rapid union. An objection is that the resistance of the caput will be impaired with unsatisfactory securing of the nail as a result.

Harris (1943) suggested that the nail should be placed along the longitudinal axis of the collum through the acetabular internal cortex. Furthermore, he inserted a trans-articular graft but was not satisfied with the fixation and therefore applied a plaster hip spica. He believed that rotation still may be possible and drilled a Kirschner wire through the distal femur with the ends outside the plaster. The immobilization in plaster continued for four months. A main complication is the limited mobility of the knee joint which often occurs.

Karlen (1944) and Ehalt (1954) were of the opinion that the nail should be inserted 4 cm into the pelvis. The latter recommended a nail of the Böhler type which is slightly coarser than an ordinary three-flanged nail. None of the authors discuss how to reach the desired depth. Arriola (1952) who used a van Ness nail said that *ohne Zweifel ist die Länge und Dicke des Nagel ein wichtiger Faktor der Fixierung*.

In his textbook on orthopaedic surgery Lange (1951) described the

drilled in the acetabular roof. The nail will then be easier to hammer in and the osteogenesis will improve according to the principle of Beck drilling in pseudoarthrosis. He also designed a special shape of the three flanged nail. Mayr (1953) reported a series of 167 cases of arthrodesis where in four cases the nail could not be hammered in because of a sclerotic acetabulum. In one of these the acetabulum fractured.

e) The rate of post-operative subtrochanteric fractures is rather high. Bailey & Jackson Burrows (1939) suggested that a short hip spica should be kept on for a long period because of the risk of subtrochanteric fractures. Lindstrom (1956) had one fracture in 41 cases followed up. Chapchal (1962) had two fractures in 91 cases and in another series of 114 there were five subtrochanteric fractures. Haw (1964) had three in 30 cases and Merle d'Aubigne (1964) had 13 subtrochanteric fractures in his series of 240 cases. Four of these occurred at the site of the insertion of the three flanged nail. This was one reason for his changing over to fixation with screws. Ehalt (1954) suggested a nail and plate to avoid the fracture, a method which also was supported by Gardiner (1962) and Crawford Adams (1966). Gardiner performed V arthrodesis on his series and had 7 fractures in 54 cases. Verheugen & Navarre (1964) reported 70 cases, 28 of which were stabilized with double three flanged nails and 42 with a single one. The rate of fractures among the first ones was 21.4 per cent and the latter 4.7 per cent. The weakening of the proximal femur caused by insertion of the three-flanged nail increases considerably when a parallel nail is introduced in addition.

2 Other Methods with Trans Articular Nailing

The technique of osteosynthesis with a trans articular nail has been modified by many surgeons. Kuntscher (1953) pointed out that one nail is unsatisfactory as it does not prevent rotation. He recommended stabilization with two curved nails. In his opinion one nail could possibly suffice provided that it is curved. A plaster hip spica is not required; instead mobilization can commence after two weeks. He suggested furthermore that the caput acetabulum should be drilled in a coneshaped bore in order to avoid stress concentration and referred to Martin's experiments. Lechten (1956) operated on 16 cases according to Kuntscher's method. On the radiographs only ten revealed union and four slipping of the nail. Weiss & Munzenberg (1962) published a critical article with a series of 30, out of which only 4 united. Witt (1965) criticized Kuntscher and pointed out that on the pictures demonstrating his technique the nail did not lie in the bone but inside the true pelvis which results in an unsatisfactory securing of the nails.

Radulescu (1964) suggested a completely different position. He inserted the three flanged nail from behind through the caput into the acetabular portion of the pubic bone. He believed that the conventional position will not prevent rotation, on the contrary to his technique. The method has been tried on specimens, but no comparative experiments on stability have been carried out. The described position means that the nail will penetrate the thin cortical layer of the caput and that the bone available is not fully utilized.

b *Complications*

The risks of complications which may arise are

a) fracture at insertion, b) nutritional disturbances c) diastasis of the joint, d) difficulties to insert the nail into the acetabulum e) subtrochanteric post operative fractures

All these complications can be more or less referred to the shape and the size of the nail

a) The risk of splitting the femur at insertion is especially pronounced when using three flanged nails of a coarser dimension. For instance, Burns for this reason changed over from a nail which had a diameter of 20 mm to a thinner one. It is also essential to prepare the entrance into the femoral cortex carefully, which Watson Jones (1956) and Chapchal (1965) amongst others have pointed out. When the cortex of the femur is fractured, the securing of the nail will be impaired (Karlen 1944 Nystrom, 1944)

b) Disturbances of the nutrition in connection with osteosynthesis of femoral neck fractures have been mentioned (Compere & Lee 1940 Linton, 1944 Brodetti 1961). Campell (1937) reported that the nail disturbs the nutrition partly through direct vascular lesions, partly by preventing revascularization. Furthermore when arthrodesis is contemplated, the nutrition of the caput and the acetabulum is already disturbed in many cases. Merle d'Aubigne (1964) warned against extensive dissection of the proximal femur as this may result in necrosis of the femoral head.

c) Several authors mention that diastasis easily occurs in the joint when the nail is hammered into the acetabulum. Generally diastasis is overcome by some blows with the hammer against the greater trochanter after the nail has been put into place (cf Mayr 1953). Lindstrom uses a modified nail extractor with which he compresses the head against the acetabulum. Unander Scharin (1965) has described the instrument. Crawford Adams applies a screw across the joint parallel and above the guide-wire in order to avoid diastasis.

d) Sometimes it may be difficult to hammer the nail into the acetabular roof. Karlen (1942) suggested that in these cases several bores should be

not fully utilized to secure the nails and the resistance of the bone will become further impaired by the trauma caused by the drilling

Stinchfield & Cavallaro (1950) had a series of 117 cases in which the mean rate of non union was 23 per cent Of 11 cases stabilized with a three flanged nail combined with intra juxta articular arthrodesis all but one united Of 10 patients on which fixation was carried out by using three thin Vitallium nails in different directions all united

3 Screw Reinforcement

Osteosynthesis with screws is mainly used in France and Italy Zanoli (1935) described a trans articular screw which together with a plate is fixed to the femur Putti (1938) described a simple trans articular screw without a plate Delitala (1946) and Casuccio (1946) have also designed transarticular screws The latter stabilizes with two screws which are placed at an angle to each other

In their clinical series where the fixation was done by using a trans articular screw with a femoral plate Branchiforti & Lanciotti (1957) reported 4 cases of non union out of 31 Genovesi (1964) who used a trans articular screw with or without a femoral plate sometimes in combination with osteotomy reported 32 operations and a nonunion rate of 40 per cent Cozzolino (1960) described 35 cases stabilized according to Delitala and obtained union in 94 per cent The patients were immobilized for five months Ciuccarelli & Marchi (1962) used two screws for fixation In a series of 79 cases the union amounted to 71 per cent in addition 21 per cent were relieved of pain Teinturier (1966) used 3 or 4 screws one of which is placed in an ischio femoral position

Schumpelik (1955) found mechanical deficiencies when stabilizing a fractured collum with a three flanged nail The nail only gave support at one fixed point which is the lateral layer of the cortex The author in his opinion had a superior technique of osteosynthesis He used a supporting coarse screw and a more cranially placed thinner screw connected to the former with a metal plate The upper screw is subjected to tensile stress and prevents the caput from slipping The described technique of osteosynthesis has been employed by Henssge (1967) for arthrodesis of the hip No spica is applied The author has refrained from publishing the clinical results To start with Merle d'Aubigne (1962-1965) used a three flanged nail of the van Nes type but later changed to two screws and then again to three screws always in combination with plaster immobilization In calculating the percentage of union in relation to each technique of fixation he found that in a series of 195 operated cases there was fusion in 76.84 and 89.5 per cent respectively

Witt (1956) has invented his own type of double nail. A three flanged nail is inserted in a superior-posterior direction and then a thinner nail is introduced into a hole of the coarser nail, close to its head and at a pointed angle. The thinner nail will then be hammered into the relative centre of the acetabulum. The author believed that by using this method he could reduce the time of immobilization from between 16 and 20 weeks to between 6 and 8 weeks. He mentioned however, that it must not be expected that even this technique will ensure an absolute primary stabilization, due to the thin, often sclerotic, iliac bone.

Piatkowski (1959) stressed upon the unsatisfactory fixation obtained by the use of a three-flanged nail. His technique is to introduce a three-flanged nail lengthwise into the collum through the internal acetabular layer, and a second nail of the same type in a transversal direction. No mention is made as to the dimensions used. If nails of the conventional type are used (diameter about 13 mm) it must be difficult, sometimes impossible to fit them inside the cortex of the collum. An impairment of the bone construction will result due to a large amount of the bony substance being destroyed.

Alvik (1962) combined the three flanged nail with a plate which was formed individually at the operation and placed over the joint reaching from the anterior superior iliac spine to the ventral surface of the proximal femur. It is secured with several screws. The author kept the patient immobilized in a short hip spica for four months, but permitted weight bearing already after 3-4 days. In 45 cases there was no pseudarthrosis.

At osteosynthesis of a fractured femoral neck, several authors contemplated using a few thin nails for stabilization. This would mean a reduced risk of unsatisfactory nutrition and a better fixation. Nystrom (1944) thus prefers osteosynthesis with three thin nails. Compere & Lee (1942) showed by their experiments that several threaded stainless steel wires gave a very good fixation in the collum fractures. Similar experiments were also carried out by Harmon and coworkers (1948) and by Deyerle (1965). This technique has not been used in arthrodesis to the same extent. Blount (1956) described the so called pin and dowel arthrodesis. Several — four or five — pins are hammered into the greater trochanter and spread inside the ilium. Blount approved of this technique if prior to the operation, the mobility of the hip was limited. Smith and coworkers (1949) used three nails. The technique was varied inasmuch as the nails were hammered from the inside of the ilium out into the caput. The reason of this has not been expressed. Of 14 patients who were operated upon 12 united. In one patient the nail slipped into the pelvis. A number of drilled bores in the caput and the acetabulum would improve the union according to the author. In the described method the bone material is

not fully utilized to secure the nails and the resistance of the bone will become further impaired by the trauma caused by the drilling

Sunchfield & Cavallaro (1950) had a series of 117 cases in which the mean rate of non union was 23 per cent Of 11 cases stabilized with a three flanged nail combined with intra juxta articular arthrodesis all but one united Of 10 patients on which fixation was carried out by using three thin Vitallium nails in different directions all united

3 Screw Reinforcement

Osteosynthesis with screws is mainly used in France and Italy Zanolli (1935) described a trans articular screw which together with a plate is fixed to the femur Putti (1938) described a simple trans articular screw without a plate Delitala (1946) and Casuccio (1946) have also designed transarticular screws The latter stabilizes with two screws which are placed at an angle to each other

Particularly in osteosynthesis with screws it would seem necessary to utilize the multi point fixation. The reason being that the circular cross section of the screw will not prevent rotation around its longitudinal axis. Furthermore, the moment of inertia for a screw is less than that for a three flanged or a four-flanged nail of the same dimension. Consequently, it will have a smaller resistance to bending stress. The screw is superior to the nail due to its greater ability to resist tensile stress in its longitudinal axis. In arthrodesis of the hip there is no stress of this type but instead the body weight and muscular force have a compressing effect. The motives assigned to preferring screw reinforcement thus seem diffuse.

4 Intra-Medullary Nails

Several authors have tried to perform arthrodesis with one nail into the medullary cavity of the femur. According to Schneider, a long broad nail is driven in from the crest of the ilium and through this down into the femoral shaft. May & Mauck (1962) using that technique had four satisfactory fusions out of six operated cases. Mobilization with weight bearing began two weeks after the operation.

A notable difficulty with the intra medullary methods is that the elongation of the femoral diaphysis will be lateral to the ilium. Kuntscher (1957) suggested transversal osteotomy through the collum/caput and the acetabulum to obtain a better position. The lower part of the pelvis and the femur will then be medially displaced and an intra medullary nail can be driven through the ilium into the femoral shaft.

Dwyer (1964) also used a Kuntscher nail from the crest of the ilium into the femoral shaft. He obtained medial displacement by fracturing the acetabulum and sliding in the caput. In 9 cases out of 10 there was fusion. One of the disadvantages of stabilization with an intra medullary nail is the difficulty of getting the nail into position. Thus in three of these cases an unsatisfactory position of the hip resulted as the abduction and outward rotation was too great. The author pointed out that the Kuntscher nail does not prevent movements around its longitudinal axis.

Onji et al (1965) also used a straight nail which is driven in from the iliac crest into the femur. Of 18 cases 16 united. The authors pointed out the difficulty of getting the correct position in the arthrodesis. Rutt (1958) was sceptic against the intra medullary nail and thought that it was used too often and freely. His experience had been bad due to complicating infections.

De Palma and coworkers (1962) considered the hip in its normal anatomical position as the most suitable for arthrodesis. Thus they did not resect the caput nor did they perform osteotomy of the pelvis or similar

procedures. The authors stabilized with a nail plate which was hammered into the femoral shaft and attached to the ala ili with through bolts. Earlier screws were used for the fixation but after a short period they detached from the ilium. Of 15 cases two of which had been re-operated after an unsuccessful Schneider arthrodesis one did not unite. De Palma declared that there will be compression in the arthrodesis caused by the body weight and the muscular force.

5 Osteosynthesis with Compression

Several authors have insisted that union will be more rapid and secure if the osseous surfaces are subjected to compression. Others inter alia, Andersson (1965) are not of the opinion that the osteogenesis would improve by compression.

Compression may also contribute to better stability. The osteosynthetic material has consisted of nails, screws and plates.

Axér (1961) and Fox (n.d.) have independently designed a compression nail following the same principle. The nail is driven in from the greater trochanter up through the collum caput penetrating the internal cortex of the acetabulum where it is locked with a stop plate. On the trochanter side the end of the nail is threaded and a plate is slipped over which rests against the cortex of the femur. Then a coil spring is passed over the nail end and finally a nut is threaded on. In this way there will be a continuous compression in the arthrodesis.

Axér (1961) reported 19 cases. Out of these 7 were further stabilized with a hip spica for two to four months. According to the author immobilization in plaster is not always necessary. 6 cases were re-operated. In 5 cases (26 per cent) there was no fusion. Fox has not published any clinical results.

Langenskiöld & Laurent (1967) reported a series of 13 cases operated with Axér's method. In 10 of these the follow up was long enough to allow assessment. All of these were fused. Plaster was not used and mobilization began the day after the operation. Already in 1945 Niebauer designed a compression device according to the above principle (personal communication 1967).

Ostapczuk (1964) described a nail which is driven into the ilium through the acetabular roof. There is a hole in the tip of the nail. A pin is threaded from the outside of the ilium into the hole of the nail thus locking it. A nut is used to bring about compression. Five cases were operated without complications. No mention is made of the rate of fusion.

Mac Kee (1957) utilized a coarse screw for the osteosynthesis. It is screwed into the acetabular roof. The part of the screw on the femoral

Particularly in osteosynthesis with screws it would seem necessary to utilize the multi point fixation. The reason being that the circular cross section of the screw will not prevent rotation around its longitudinal axis. Furthermore, the moment of inertia for a screw is less than that for a three-flanged or a four-flanged nail of the same dimension. Consequently it will have a smaller resistance to bending stress. The screw is superior to the nail due to its greater ability to resist tensile stress in its longitudinal axis. In arthrodesis of the hip there is no stress of this type but instead the body weight and muscular force have a compressing effect. The motives assigned to preferring screw reinforcement thus seem diffuse.

5 Osteosynthesis with Compression

Several authors have insisted that union will be more rapid and secure if the osseous surfaces are subjected to compression Others inter alia Andersson (1965) are not of the opinion that the osteogenesis would improve by compression

Compression may also contribute to better stability The osteosynthetic material has consisted of nails screws and plates

Axer (1961) and Fox (n d) have independently designed a compression nail following the same principle The nail is driven in from the greater trochanter up through the collum caput penetrating the internal cortex of the acetabulum where it is locked with a stop-plate On the trochanter side the end of the nail is threaded and a plate is slipped over which rests against the cortex of the femur Then a coil spring is passed over the nail end and finally a nut is threaded on In this way there will be a *continuous* compression in the arthrodesis

Axer (1961) reported 19 cases Out of these 7 were further stabilized with a hip spica for two to four months According to the author immobilization in plaster is not always necessary 6 cases were re-operated In 5 cases (26 per cent) there was no fusion Fox has not published any clinical results

Langenskiöld & Laurent (1967) reported a series of 13 cases operated with Axers method In 10 of these the follow up was long enough to allow assessment All of these were fused Plaster was not used and mobilization began the day after the operation Already in 1945 Niebauer designed a compression device according to the above principle (personal communication 1967)

Ostapczuk (1964) described a nail which is driven into the ilium through the acetabular roof There is a hole in the tip of the nail A pin is threaded from the outside of the ilium into the hole of the nail thus locking it A nut is used to bring about compression Five cases were operated without complications No mention is made of the rate of fusion

Mac Kee (1957) utilized a coarse screw for the osteosynthesis It is screwed into the acetabular roof The part of the screw on the femoral

side of the joint is smooth so that it will easily slide into the bone tunnel drilled in the collum/caput. By means of a plate and a nut compression is caused. In view of the fact that the screw, running through the collum/caput is smooth with a circular cross section, it is unable to resist torque. The clinical report is favourable, however. Out of 50 operated cases 94 per cent united.

Charnley (1953) also used a compression screw. He tried to maintain the compression with a coil spring. In his first series 13 out of 15 cases united. The healing is not verified by X-ray and probably also includes what the author calls *fibrous union*. Morris (1962) using Charnley's method distinguished between clinical and radiographically verified healing. In a follow-up series of 55 cases he found union on the radiographs in 80 per cent when a plaster hip spica had been applied, and in 60 per cent when no plaster was used. The clinical healing, i.e. abolishment of pain on the other hand, was 86 and 90 per cent, respectively. Mortens & Jensen (1960) had improved patients in 33 out of 39. Only 17 of these 33 revealed fusion. Charnley (1955) reported fusion in 50 per cent. Debeyre (1958) stated 42 per cent and Piggot (1960) in 71 per cent.

Thompson (1963) did not approve of Charnley's technique and received the statement with scepticism that the so called fibrous healing afforded as good a result as the radiographically verified fusion.

A complication, following the operation according to Charnley's technique is fracture of the femoral neck which by Morris (1966) was stated to occur in 9 per cent in a series of 55. Herbert (1960) made a theoretical analysis of the forces in a normal hip and a fused hip. He found that in a fused hip, the femoral neck was influenced by great forces. He calculated the compression and tensile stress at about 250 kp/cm^2 when the patient stands on one leg without a nail. This stress is reduced with 20 per cent using a three-flanged nail, and with 10 per cent when the nail has a circular cross section.

The compression lessens and quickly disappears after the operation. Charnley found that without spring loading the compression had disappeared already during the first post operative days. Morris stated that also the spring loaded compression screw lost its effect during the first post-operative weeks. Rydell's investigation (1965) revealed that the caput is subject to considerable stress even when the patient lies in bed because of the muscular activity required to lift the healthy leg for instance. Thus compression develops in the joint without any special device. Pelvic osteotomy and compression belong to the method elaborated in Switzerland and designated the AO technique (Muller 1953 1967 Gertsch 1966). After performing osteotomy in the upper edge of the acetabulum

a plate is screwed to the outside of the ilium. The plate contacts the lateral side of the chiselled greater trochanter and the proximal femoral shaft. The plate is shaped individually at the operation if necessary. No plaster immobilization is used and after three weeks mobilization begins. The clinical results have not yet been published. The great problem here as in the earlier mentioned intra medullary methods is to obtain the desired position of the arthrodesis. No mention is made of the difficulty in achieving a satisfactory attachment of the screws in this weak part of the ilium with its thin cortical layers. This also applies to other methods where plates are used for stabilization.

Stone (1956) applied a simple plate across the cranial part of the joint down to the greater trochanter. The plate is supposed to give compression. He immobilized for four months in plaster. The author reported good clinical results with a union rate of 95 per cent in an operation series of 41 cases. Daubenspeck (1966) screwed two plates to the upper part of the joint and used immobilization for six weeks. He believed that compression in the joint occurred by the spring load of the plates.

6 Other Methods

A method which completely differs from those earlier mentioned has been elaborated by Kirkaldi Willis and coworkers (1958). The caput is fixed to the pelvis with a staple over the joint. A singular staple is from the mechanical points of view an unsatisfactory solution to the problem of stabilization. The forces arising will be transferred to a very small part of the bone with too great a stress in the bone as a result. The clinical results stated at a fusion rate of 54 per cent in a series of 37 cases also suggest unsatisfactory stability.

6 Other Methods

A method which completely differs from those earlier mentioned has been elaborated by Kirkaldy Willis and coworkers (1958). The caput is fixed to the pelvis with a staple over the joint. A singular staple is from the mechanical points of view an unsatisfactory solution to the problem of stabilization. The forces arising will be transferred to a very small part of the bone with too great a stress in the bone as a result. The clinical results stated at a fusion rate of 54 per cent in a series of 37 cases also suggest unsatisfactory stability.

IV Subtrochanteric Osteotomy in Arthrodesis

The osteosynthesis in arthrodesis of the hip will be subject to great stress because of the long lever formed by the femur. One way of increasing the relative stability of the osteosynthesis would thus be to eliminate the lever. This idea has caused several authors to suggest shortening of the lever by subtrochanteric osteotomy.

F. R. Thompson (1956, 1961) is spokesman for this. He claims that following arthrodesis of the hip the femur with the caput acting as a fulcrum has a lever effect of 23:1. The shaft is approximately 35 cm and the radius of the caput approximately 1.5 cm (cf. Figure 1 a). By merely stating these figures a correct assessment of the problem cannot be made. This relation 23:1, is furthermore incorrect. The centre of the caput does not act as a fulcrum but instead the mechanical model beam with built in end is applicable. Loading of the femur will cause both bending moment and torque of the nail. Provided that the collum/caput is fixed with a nail in the longitudinal direction of the collum, Fig. 1 b illustrates that in subtrochanteric osteotomy, the eliminated lever will be shorter than the 35 cm calculated by Thompson. However the full effect of the muscular force has been neglected here. In subtrochanteric osteotomy the adductors and the dorsal flexors as well as the rectus femoris muscle and the major gluteal muscle are eliminated but the medium and minor gluteal muscles, the short rotators and also the iliopsoas muscle still act (cf. Fig. 2).

Originally, osteotomy was suggested in cases of tuberculosis. Abbott (1931) described a technique where the hip was widely abducted to make the adductor muscles cause compression. Correcting osteotomy was performed at a second operation and the position was gradually adjusted. This technique was especially adopted for children with tuberculosis. Farkas (1939) used osteotomy in cases of tuberculosis in the hip to achieve a more rapid healing.

Blauth & Mau (1960) reported in a series of 21 cases 9 cases of non union 4 of which in the hip 2 in the osteotomy and 3 both in the hip and the osteotomy. They considered it disadvantageous that two operations must be performed and that the time of immobilization is long (4 months) and the shortening of the leg pronounced (3.7 cm on an average).

King (1952) performed osteotomy to correct the position. He used a plate for internal fixation to avoid a hip spica. Ling (1958) also regarded

Fig 1 a The leverage 23:1 is supposed to be eliminated at subtrochanteric osteotomy (According to F. R. Thompson)
 Fig 1 b a_1 = leverage for torsion around nail reduced by a_2 at subtrochanteric osteotomy
 b = eliminated part of leverage for bending moment in subtrochanteric osteotomy
 P = the assumed point of action of force O = place of osteotomy
 N.B. Only the leverages in the frontal plane are calculated

the osteotomy as important to correct the position and to reduce the risk of adduction appearing in the arthrodesis.

The main indication for osteotomy is to reduce the mechanical stress. Wilkinson (1946), Cholmeley (1956) and Thompson (1956) suggested this as a routine procedure in arthrodesis of the hip. The latter reported a series of 34 cases on which osteotomy was carried out at a rate of non union amounting to 12 per cent. 3 in the arthrodesis, 1 in the osteotomy. In a comparative series of 20 cases without osteotomy the rate of non union was 70 per cent. Internal fixation was not used. The author mentioned that non union in the osteotomy is difficult to treat but that it is a rare complication. When the paper was read it was criticized by Smith who pointed out that osteotomy possibly eliminated the stress in the arthrodesis for some time. The reduced stress may disappear early if the osteotomy heals. He stated that in his own series he obtained union in 87 per cent without osteotomy. In a series of 103 patients who were arthrodesed according to different methods, Williams (1962) reported unsuccessful results in 60 per cent using ileo femoral grafting. Osteotomy reduced this figure to 23 per cent.

Lipscomb & McCaslin (1961) published the series from the Mayo Clinic. They recommended Thompson's technique and a full length hip spica for four months. Then mobilization with a short spica for two more months. Of the patients treated according to this schedule the majority did not regain more than 70 degrees of flexion in their knee. The average

IV Subtrochanteric Osteotomy in Arthrodesis

The osteosynthesis in arthrodesis of the hip will be subject to great stress because of the long lever formed by the femur. One way of increasing the relative stability of the osteosynthesis would thus be to eliminate the lever. This idea has caused several authors to suggest shortening of the lever by subtrochanteric osteotomy.

F. R. Thompson (1956, 1961) is spokesman for this. He claims that following arthrodesis of the hip the femur with the caput acting as a fulcrum has a lever effect of 23:1. The shaft is approximately 35 cm and the radius of the caput approximately 1.5 cm (cf. Figure 1 a). By merely stating these figures a correct assessment of the problem cannot be made. This relation, 23:1, is furthermore incorrect. The centre of the caput does not act as a fulcrum but instead the mechanical model beam with built-in end is applicable. Loading of the femur will cause both bending moment and torque of the nail. Provided that the collum/caput is fixed with a nail in the longitudinal direction of the collum. Fig. 1 b illustrates that in subtrochanteric osteotomy, the eliminated lever will be shorter than the 35 cm calculated by Thompson. However, the full effect of the muscular force has been neglected here. In subtrochanteric osteotomy the adductors and the dorsal flexors as well as the rectus femoris muscle and the major gluteal muscle are eliminated but the medium and minor gluteal muscles, the short rotators and also the iliopsoas muscle still act (cf. Fig. 2).

Originally, osteotomy was suggested in cases of tuberculosis. Abbott (1931) described a technique where the hip was widely abducted to make the adductor muscles cause compression. Correcting osteotomy was performed at a second operation and the position was gradually adjusted. This technique was especially adopted for children with tuberculosis. Farkas (1939) used osteotomy in cases of tuberculosis in the hip to achieve a more rapid healing.

Blauth & Mau (1960) reported in a series of 21 cases, 9 cases of non-union, 4 of which in the hip, 2 in the osteotomy and 3 both in the hip and the osteotomy. They considered it disadvantageous that two operations must be performed and that the time of immobilization is long (4 months) and the shortening of the leg pronounced (3.7 cm on an average).

King (1952) performed osteotomy to correct the position. He used a plate for internal fixation to avoid a hip spica. Lange (1958) also regarded

according to the above technique one did not unite while in a series of 33 cases without osteotomy fusion did not occur in 20 cases. Guilleminet and coworkers (1965) performed arthrodesis according to Davis method with a pedicle crista graft. The authors stated that it is not necessary to perform osteotomy as a routine.

Morris (1962) published a series operated upon according to Charnley's technique. He believed that osteotomy may reduce stress in the arthrodesis and thus increase the rate of fusion but that it may not reduce the time required for immobilization in plaster and for the union. Hobler (1964) also was of the opinion that osteotomy will not guarantee a shorter healing period or union at a higher rate. There is a great risk that non union will occur in the osteotomy if the arthrodesis fuses. Jones & coworkers (1956) advocate that osteotomy causes further problems and doubted whether the osteotomy by eliminating mobility and stress in the hip can accelerate fusion of the joint. In these authors' view the osteotomy heals prior to the arthrodesis.

Nixon and coworkers (1962) reported 13 cases operated according to Davis technique. In 2 cases the arthrodesis did not unite and in 1 case the osteotomy. Stabilization was carried out with plaster for about 15 weeks but without nailing. 6 of the patient could flex their knee at a maximum of 90 degrees. Decoultx (1965) modified Davis technique and had 2 cases of non union out of his 10 patients operated upon.

Genovesi (1964) followed up 32 cases of arthrodesed hip where stabilization was done by means of one or two trans articular screws. In 29 cases osteotomy was performed and 11 cases of non union resulted (38 per cent). Cauchoux (1965) published a series of 95 cases in 22 of which osteotomy was performed. In the entire series there were 15 cases of non union one of which in the osteotomy. Out of the 14 non united 4 belonged to the group subjected to osteotomy. The rate of non union in the group of osteotomy was thus 28.6 per cent. In the group where no osteotomy was performed the percentage was 13.6.

Summing up the opinions are extremely controversial with regard to the results and the advantage of osteotomy. When intertrochanteric osteotomy has been performed as the only procedure in osteoarthritis of the hip a rate of non union amounting to between 12 and 13 per cent is reported despite internal fixation (Crellin & Simurda 1965, Rousborough & Stiles 1967, Scott 1967, Hirsch & Goldie 1967). The risk of non union ought to be greater in subtrochanteric osteotomy which is performed as a supplement in arthrodesis of the hip where merely a hip spica is used for the stabilization. By introducing osteotomy in arthrodesis of the hip attempts have been made to solve one problem — by creating another.

Fig 2 a b c
Muscular insertions at proximal end of
femur (Copied from Rauber Kopsch)

rate of fusion was 81 per cent without osteotomy and 88 per cent with osteotomy

Apley & Denham (1955) stabilized with a three flanged nail and performed subtrochanteric osteotomy with traction treatment for six weeks. Then the patient was allowed to move about with a short hip spica for another six weeks. The advantage of osteotomy was expressed as follows:

Movement is thus transferred from a site where bone union is difficult and doubtful to one where it is easy and probable. Out of 23 cases treated

OWN INVESTIGATIONS

General Aspects

The shape and physical properties of the reinforcement and of the object which is to be fixed, are decisive for the stability. In arthrodesis of the hip it is thus the anatomical structure and the physical properties of the bone as well as the technical data of the osteosynthetic appliance which determine the efficiency of the osteosynthesis.

The conditions afforded by the bone are set. The appliance can be adapted to suit different demands. Without doubt it is possible to achieve resistance of the appliance which would be superior to that of the bone. The weakness in the construction will thus be the bone. Consequently, the appliance must be designed so that the bone can carry a maximum of the transferred forces. This is done by avoiding stress concentration and distributing it in as large an area as possible.

The bone is a visco elastic material. The deformation depends on the magnitude, speed and duration of the load (Sedlin 1965, Sedlin & Hirsch, 1965). If a certain load is exceeded, a longstanding deformation may occur and with even heavier loads fractures may result. The prospects of a stable osteosynthesis will then be considerably impaired. This means that there will be greater movement between the bone surfaces which are to be fused. The effect of the osteosynthesis is no longer the desired.

The extent of mobility between the articular surfaces in the arthrodesed hip when loading the femoral diaphysis has in this investigation been used to determine the degree of stability. On this basis an experimental technique has been elaborated.

Theoretical Basis of Measuring Technique

When elaborating the measuring technique the acetabulum has been regarded as the inside of a hemisphere in which the caput articulates. The caput is regarded as a sphere its radius is assumed to be R (Fig. 3).

A perpendicular coordination system is placed so that the xy plane will cover the edge of the acetabulum with the y axis passing from the anterior

OWN INVESTIGATIONS

General Aspects

The shape and physical properties of the reinforcement and of the object which is to be fixed, are decisive for the stability. In arthrodesis of the hip it is thus the anatomical structure and the physical properties of the bone as well as the technical data of the osteosynthetic appliance which determine the efficiency of the osteosynthesis.

The conditions afforded by the bone are set. The appliance can be adapted to suit different demands. Without doubt it is possible to achieve resistance of the appliance which would be superior to that of the bone. The weakness in the construction will thus be the bone. Consequently, the appliance must be designed so that the bone can carry a maximum of the transferred forces. This is done by avoiding stress concentration and distributing it in as large an area as possible.

The bone is a visco elastic material. The deformation depends on the magnitude, speed and duration of the load (Sedlin 1965, Sedlin & Hirsch, 1965). If a certain load is exceeded, a longstanding deformation may occur and with even heavier loads fractures may result. The prospects of a stable osteosynthesis will then be considerably impaired. This means that there will be greater movement between the bone surfaces which are to be fused. The effect of the osteosynthesis is no longer the desired.

The extent of mobility between the articular surfaces in the arthrodesed hip when loading the femoral diaphysis has in this investigation been used to determine the degree of stability. On this basis an experimental technique has been elaborated.

Theoretical Basis of Measuring Technique

When elaborating the measuring technique, the acetabulum has been regarded as the inside of a hemisphere in which the caput articulates. The caput is regarded as a sphere its radius is assumed to be R (Fig. 3).

A perpendicular coordination system is placed so that the xy plane will cover the edge of the acetabulum with the y axis passing from the anterior

The rotation of the caput is determined also in components around the respective axes

$$\overbrace{Z} \quad p = \frac{c_1 - a_1}{2}$$

$$\overbrace{X} \quad q = b - \frac{a + c}{2}$$

$$\overbrace{Y} \quad r = a - \frac{a + c}{2}$$

p q and r are defined as a rotation movement around each axis at the distance R from the centre. They are calculated as distances and bound to the xy yz and xz plane through the centre

For point D the translation along the x and z axes will be

$$d_1 = b_1 + c_1 - a_1$$

$$d = a + c - b$$

Point E is calculated in the respective directions of the axes

$$x = x_0 - r \quad y = y_0 + q \quad z = z_0$$

$$x_1 = b_1 + \frac{c_1 - a_1}{2} - a + \frac{a + c}{2}$$

$$y_1 = \frac{a_1 + c_1}{2} + b - \frac{a + c}{2}$$

$$z_1 = \frac{a + c}{2}$$

The relative movement between the caput and the acetabulum in the given points is obtained by compiling the measured and the calculated coordinates. In points A B C and D the movement is calculated in the plane to which the two coordinates belong

$$S = |s_1 + s|$$

In point E the translation will consist of movements in all the coordinate directions

$$S = |x + y + z|$$

The movement in each point is obtained as follows

$$S_1 = |a_1 + a|$$

$$S_p = |b_1 + b|$$

$$S_c = |c_1 + c|$$

$$S_d = |d_1 + d|$$

$$S_E = |x_E + y_1 + z_1|$$

Thus comparative figures have been obtained for the movement be

Fig 4 Direction of measurements for each gauge a_1 a_2 b_1 b_2 c_1 c_2 Measuring point B placed at the acetabular edge below the anterior iliac spine

Calculations

A body of the assumed shape and with the described initial position can be subjected to rotation and translation. This means that the caput can turn in or slip out from the acetabulum.

The changed positions between the caput and the acetabulum due to load, are measured in the points A, B and C. In each point the movement is recorded in two planes. Point A: x_1 , y_1 ; point B: x_2 , y_2 ; point C: x_3 , y_3 . The measured magnitudes are designated a_1 , a_2 , b_1 , b_2 , c_1 , c_2 (Fig 4).

The centre of the caput is designated T (x_0 , y_0 , z_0). Thus the initial position coincides with the origin. The translation along the respective axes is calculated accordingly:

$$z_0 = \frac{a_1 + c_1}{2}$$

$$x_0 = b_1 + \frac{c_1 - a_1}{2}$$

$$y_0 = \frac{a_2 + c_2}{2}$$

Experimental Device

The described calculation method is based upon certain measured data. These have been obtained by the use of a specially designed experimental device. It consists of a stand on which the specimen is mounted in the desired position. The arthrodesis can be done using the osteosynthetic technique to be tested. The device also has measuring and recording equipment. The measuring component shows the distance deviation between one point on the acetabular edge and the corresponding points on the femoral head. The measuring is done in the earlier defined points A, B and C and in each of these performed in two planes. One is a joint plane for the three points and consists of the earlier defined xy plane. The measuring is thus performed along the acetabular edge and in perpendicular planes to this measuring direction, i.e. in points A and C in the xz plane and in point B in the yz plane.

Mounting the Specimen

The stand consists of four iron corner columns which are mounted in a cement foundation and at the top joined by a sturdy metal plate (Hirsch 1951). Between the columns displaceable beams are placed in the vertical plane. On these beams a thick wooden board is fitted with sturdy screw joints. The board is adjustable. The pelvic specimen is fixed to the board with three sturdy through bolts (Figs 5 and 6).

A swivel arm is fitted at right angles to each column of the stand. Between these arms there is a cross beam with a pulley in which the load wire runs. The load can be applied to affect the desired directions: flexion, abduction, extension and adduction. On the swivel arms fitted to the columns there is a supporting arm system which carries the mechanical unit and the extensometers. This system is designed to allow adjustment of the extensometers.

Application of the Load

The load is applied to the femur in the horizontal plane (Fig. 7). The point of application is set at a fixed distance from the upper edge of the caput to a point on the femur. The distance is measured by means of a

tween the caput and the acetabular surfaces in each measured point. The essential for the further study is the maximum movement, measured to be $S_{(1-F)_{max}}$. This value is selected and used with the designation S_{max} in the movement loading diagrams. The diagram is obtained by plotting the S_{max} as a function of the load.

Experimental Device

The described calculation method is based upon certain measured data. These have been obtained by the use of a specially designed experimental device. It consists of a stand on which the specimen is mounted in the desired position. The arthrodesis can be done using the osteosynthetic technique to be tested. The device also has measuring and recording equipment. The measuring component shows the distance deviation between one point on the acetabular edge and the corresponding points on the femoral head. The measuring is done in the earlier defined points A, B and C and in each of these performed in two planes. One is a joint plane for the three points and consists of the earlier defined xy plane. The measuring is thus performed along the acetabular edge and in perpendicular planes to this measuring direction, i.e. in points A and C in the xz plane and in point B in the yz plane.

Mounting the Specimen

The stand consists of four iron corner columns which are mounted in a cement foundation and at the top joined by a sturdy metal plate (Hirsch 1951). Between the columns displaceable beams are placed in the vertical plane. On these beams a thick wooden board is fitted with sturdy screw joints. The board is adjustable. The pelvic specimen is fixed to the board with three sturdy through bolts (Figs 5 and 6).

A swivel arm is fitted at right angles to each column of the stand. Between these arms there is a cross beam with a pulley in which the load wire runs. The load can be applied to affect the desired directions: flexion, abduction, extension and adduction. On the swivel arms fitted to the columns there is a supporting arm system which carries the mechanical unit and the extensometers. This system is designed to allow adjustment of the extensometers.

Application of the Load

The load is applied to the femur in the horizontal plane (Fig. 7). The point of application is set at a fixed distance from the upper edge of the caput to a point on the femur. The distance is measured by means of a

DIFFERENTIAL TRANSFORMERS NO

Fig 6 Specimen fitted to wooden board. Fixation of hip with three pins. Frontal and lateral views.

... specially designed measuring plate of transparent plastic. In the ... of the plate there is a hole through which a pin slides perpendicular to the plate. The plate is held in a vertical position. The pin is directed towards the upper edge of the caput. The lower edge of the plate will then indicate the point at which the load is applied. The lever arm has thus been kept constant.

Fig 7 Position of femur and application of load
A indicates device for determining point for application of load

Position of Specimen

The specimen was adjusted to correspond to the pelvis of an individual in a standing position. As it was impossible to obtain specimens consisting of the entire pelvis and both femurs, the individual variations could not be considered. Instead certain fixed angles and distances were decisive for the adjustment of the pelvic specimen as well as the joint

the angle between the horizontal plane and a line from the promontorium through the upper end of the symphysis 60 degrees

the angle between the sagittal plane through the symphysis and a sight line between the upper end of the symphysis and the anterior part of the sacro iliac joint 30 degrees

the angle between the horizontal plane and a sight line in the frontal plane from the upper end of the sym- physis to the anterior superior iliac spine	35 degrees
the acetabular angle according to Sharp (1961)	32—38 degrees
the transverse diameter	13.5 cm
the angle between the longitudinal axis of the femur and the sagittal plane	10 degrees
the frontal plane	20 degrees
anteversion of the collum	12 degrees
(Data from Rauber Kopsch 1952 Weinreich 1959 Her- bert 1960 Backman 1957 St Claire Strange 1965)

the sides of the stand

Measuring and Recording Equipment

Calipers

To measure the movement between the acetabulum and the femoral head, six calipers have been used (Fig 8). The ratio of these is 1:1 and thus the movement between the measuring tips corresponds to the movement occurring in the gauge which is placed between the opposite ends of the caliper. All the joints of the measuring devices are fitted with ball bearings. The calipers are assembled in pairs with a slightly elastic coupling and fitted in a specially designed frame. They are placed at right angles to each other. The leg of one of the calipers is soldered to the leg of the other using a thin sheet of metal. At the angle of this sheet of metal there is a common tip. This permits slight angular motion between the calipers. The free leg of the feeler gauge is cylindrical and its tip is fitted to a spring loaded piston which is movable in this cylinder. This is to secure a reliable contact with the specimen (Fig 9).

The joint measuring tip makes contact with a measuring point on the acetabulum. This consists of a sheet of metal, which is screwed to the pelvis and has a free end protruding from the acetabular edge. The free end is bent towards the surface of the caput so that the measuring tips will lie almost in the same plane. The sheet of metal is covered with a thin layer of plastic to prevent the caliper from sliding against the metal. The free measuring tip is pressed against the surface of the caput.

An elastic band stretched between the frame and the specimen guarantees a continuous slight pressure between the measuring tips and the base.

Displacement Gauges

The transducer used is a differential transformer manufactured by Svensk Elektronikonsult (AB Detektor) Göteborg. It is identical with that described by Rolander (1966).

The transformer consists of windings on a teflon bobbin inside which there is a movable soft iron core with a brass shaft and a measuring pointer of antimagnetic stainless steel. The length of the gauge is 40 mm with an external diameter of 8 mm. The transducer is wound as a balanced bridge and because of the electrical design it is possible to calibrate against a constant precision resistance. The linear deviation within the measuring

Fig 8 A Cal per B Displacement gauge

Fig 10 Original loading diagram The letters correspond to the respective gauges

range is less than 1 per cent The transducer has been regularly calibrated with a micrometer in the apparatus, designed by Rolander (1966)

Recording Device

The six transducers are connected to a specially designed switch monitor (AB Svenska Philips och Svensk Elektronikonsult, Goteborg) Each transducer is manually connected in turn to a carrier frequency system (Philips BF2) Each channel has its own unit for balancing and zero setting an amplifier and a calibration resistance The carrier frequency system is connected to a one-channel potentiometer recorder (Philips PR 2210 A 21) These devices have been described by Rolander (1966) (Fig 5)

After connecting each channel the recording paper is fed manually once a stabilized position is obtained Recording of each channel takes 2—3 seconds and for all six transducers 15 seconds Each loading and recording period thus requires 30 seconds The aim is to maintain this time constant in view of the visco elastic properties of the bone Besides the magnitude and the speed of the loading, the degree of deformation is dependent on the loading time (Sedlin 1965)

The sensitivity of the extensometer is adjusted so that a change in distance of 1 mm between the measuring tips corresponds to 20 scale lines on the recorder The measuring error is 0.25 per cent at full scale deflection (full scale deflection = ± 2.5 mm) The width of the recording paper is 250 mm (Fig 10)

Material

The specimens were obtained at routine autopsies at the Pathological Institute of the University Hospital and in exceptional cases at other hospitals in Goteborg They consisted of the right half of the pelvis and the

upper part of the femur including the intact hip joint and at least 15 cm of the femoral shaft. Only macroscopically normal specimens were selected from cases without any general disease of the skeleton. All specimens were x rayed and no abnormal signs were observed except slight osteoarthritic changes. The specimens were stored at minus 30 degrees C packed in air tight plastic bags. This way of storing does not affect the physical properties (Frankel 1960 Sedlin 1965 Sedlin & Hirsch 1965).

In order to assess the magnitudinal variation of the specimen certain measurements were taken. Thus the maximum and minimum diameters of the collum and the diameters of the caput were noted. Furthermore the body of the iliac bone was measured at its thinnest part. The results are tabulated (Table III).

Statistical Analysis

The statistical analysis is an assessment of the tested osteosynthetic methods with regard to the measured value S_{max} . This value has been measured under four types of loading, flexion, abduction, extension and adduction. The study was performed on a number of specimens designated No 23—112 (Table III). No values were, however, obtained for specimens No 43 and No 46, because of damaged specimens.

The magnitude of the load varied between 2 and 20 kp. It was not constant for all specimens, but depended on the magnitude of the measured displacement.

In 11 cases more than one loading series was carried out with the same osteosynthetic method. On statistical analysis of these cases the values from the original experiment were used.

The following conditions complicate a statistical analysis of the present material where the intention is to elucidate the differences in the efficiency of the methods:

1. There are great variations in the physical properties of the individual specimens.

2. A non measurable weakening may occur in the specimen after testing one method of osteosynthesis. This has an impairing effect on the conditions obtained during investigation of a subsequent method.

3. Certain experiments have been performed with different load intervals and also with different maximum loads. It is impossible to concentrate the measured value obtained for the different loading directions into one adequate expression.

An attempt has been made to overcome these difficulties by statistically analysing the material in two different ways with subsequent comparison of the results.

Sign Test

The series of experiments in which two or more methods were tested on the same specimen was studied using the so called sign test.

The measured values for the respective loading directions found at the same load for two different methods on the same specimen were recorded. One of the methods was used as a reference and the sign of the difference

between the measured values for this and the other method was determined. In this way a series of + and — signs was obtained for various pairs of methods.

On the assumption that the methods are equally good from the point of view of stability the number of + and — signs ought to be roughly the same. If the number of the type of sign (+ or —) that occurs least falls below a certain limit the assumption is rejected and the difference is said to be significantly positive or negative depending on the distribution of the signs (Brownlee 1965). An analysis of this type requires comparison of at least six observations (Table IV). This is the reason why comparisons could not be made in certain experiments despite the fact that two methods were employed on the same specimen. One method can have given such poor stability that the required number of observations could not be made. In spite of the fact that this first method was inferior to that with which it was compared it was not possible to ascertain this difference by the present method of analysis.

Table V gives a survey of the results of the sign test. It should be emphasized that this is a matter of isolated comparisons in pairs. The test was performed on a 5 per cent level. The designation Sv J refers to cases where the depth of the insertion of the three-flanged nail exceeded 30 mm.

Descriptive Calculations

The following calculation was performed in an attempt to obtain a full assessment of the series. For each method the mean values of S_m , for loads of 6, 8 and 10 kp was calculated for the loading directions investigated. These mean values were ranked within each loading direction and for each load. For each direction and load a rank sum was then calculated and finally a total rank sum for each method. From this total sum of ranks a mean rank sum was obtained by dividing by 12 (3 loads, 4 loading directions) (Table XII).

In the ranking procedure the method with the lowest mean value was ranked 1, that with the next lowest mean value 2 and so on. If the mean value happened to be identical they both received a ranking number equal to the mean value of those ranking numbers they would have received had they been slightly different.

The mean rank sum can be said to provide a quantitative measure for a given fixation type with the following reservations:

1. Variations in the physical properties of the specimens have been disregarded. These variations could be rather large as is partly illustrated by the standard deviations calculated for the three-flanged nail and three point nail fixation (Table V). The standard deviation is in the

- 2 The fact that different numbers of observations have been used in calculating the different mean values has been disregarded

The mean values within a certain direction of movement should of course increase with heavier loads. It can be seen from the tables of the mean values for the different methods that this is not always the case however. This depends on the fact that the weak specimens have been gradually excluded as the load has increased and thus not contributed to the results at higher loads (cf. Table XI).

cases calculated from the expression $\sqrt{\frac{\sum (\chi_l - \chi_r)^2}{n}}$ where χ is the deflection in the direction and load concerned χ is the mean value of all χ , and n the number of observations i.e. the number of specimens where observations were made for the different directions and loads. The table reveals high standard deviations for the three flanged nail and lower ones for the three point fixation. The high values probably depend on the specimen factor) which includes in particular the variation of the physical properties of the material. Also of importance are mechanical changes occurring in connection with the osteosynthesis itself. The latter occur to a greater extent in osteosynthesis with the three flanged nail than with the considerably thinner N nails. In addition by using three nails a smoothing effect is obtained in other words the importance of the specimen factor is greater when only one nail is used.

*) Cf. page 58

This creates the disadvantage of the first osteosynthetic procedure affecting the specimen in such a way that the conditions for the following ones will be impaired

To master this problem certain rules have been set. The method requiring the smaller amount of bone was tried before the one engaging a greater amount i.e. osteosynthesis with thinner nails was performed before using the coarser ones

When it was not quite clear which method caused the least damage the succession of the methods was varied. The method seeming to be the most inferior at the preliminary experiments was tried as the first method when the next series of experiments was carried out. The best conditions for testing were thus given the assumed inferior method

The loading level reached at each experiment depended on the degree of deformation. The intention was to evade remaining deformation. The load was increased stepwise by 2 kp and normally the load was augmented to a moment of 120 kpcm before unloading. The degree of remaining deformation after unloading was also recorded. The loadings were always done in the same succession: flexion, abduction, extension, adduction. N.B. The following abbreviations will from now on be used:

Three-flanged Sven Johansson nail = Sv J nail

Nystrom nail = N nail

Stabilization with Three-Flanged-Nail

Theoretical Analysis

Stabilization in arthrodesis of the hip with a three-flanged nail has perhaps been the most common method. Special attention has therefore been paid to this method. It is referred to in technical literature as the simple nail reinforcement and due to its simple mechanical design it can be analysed theoretically to a certain extent. The purpose of this is to elucidate guiding principles for experimental application.

This kind of analysis is complicated by the number of variable factors in the composition of the bone. The shape of the skeleton is complicated and the bone is inhomogeneous with wide variations in the material properties. These factors cannot be represented mathematically. Simplifications and assumptions must be made.

In the analysis a three-flanged nail of the Sv J type has been selected.

Assumptions

The calculations are carried out using the mechanical model: beam on elastic foundation. The deflection curve of beams on spring supports can

Experimental Study

For the following osteosynthetic procedures, the previously described testing technique was employed

A Nail Reinforcements

- 1 Three-flanged nail according to Sven Johansson
- 2 Three flanged nail + one Nystrom nail
 - a Nystrom nail in lateral medial direction (pos II, Fig 24)
 - b Nystrom nail in an antero-posterior direction (pos III)
- 3 Three Nystrom nails
 - a Three of standard dimension
 - b Two of standard dimension + one coarser nail (pos I)
- 4 Three-flanged nail + plate according to Alvik
- 5 Four flanged experimental nail + lateral medial Nystrom nail (pos II)

B Screw Reinforcement

Three trans articular screws

C Compression Methods

- 1 Compression nail according to Axel
- 2 Compression nail according to Fox
- 3 Compression nail according to Niebauer
- 4 Compression screw according to Mac Kee
- 5 Compression plate according to AO

Initially only one osteosynthetic method was performed on each specimen. However the specimens varied considerably with respect to size and resistance (These factors have in the following been denominated the *specimen factor*) Because of this variation the experimental series would have been too extensive to ensure a statistically significant result for all the methods to be tested

By using several osteosynthetic methods on the same specimens the specimen factor can be considerably reduced. Thus direct comparisons between the various osteosynthetic methods can be made

Calculations

Equations for each partial loading case are obtained by superposition of the elementary cases for concentrated force and moment according to Hetenyi: *Beams on elastic foundation*. By constructing boundary conditions the true deflection curve can be calculated. When the form of the curve has been obtained interest is concentrated on the most critical factor for the bone material i.e. the point of maximum deflection.

Maximum deflection is obtained in the actual loading cases at that point where the force and moment are concentrated i.e. at the external edge of the bone.

Formulae are devised for calculation of the edge deflection as a function of the following parameters

be represented by means of a fourth degree differential equation. In order to calculate the shape of the curve in a special case the existing boundary conditions are included in the general equation. After solving the equation the deflection is obtained as a function of parameters, depending only on the properties of the beam — and the support. The following assumptions are made

- 1 The bone material obeys Hook's law
- 2 The deflection of the material is transmitted in a finite area of the bone

The spring constant of the bone can then be calculated. On the basis of these calculations, the deflection of a nail in bone material can be determined for various degrees of loading as well as the effect of the varying nail and bone properties.

The nail penetrates two cortical layers which surround an area of spongy bone. The material is inhomogeneous and has varying physical properties in each layer. Between these layers there is no sharp boundary. The elastic resistance of the spongy bone is of little importance when considering tensile and compressive stresses. On the other hand the cortical bone has marked physical properties (Raubert 1876, Evans 1957, Sedlin 1965). Because of these conditions, calculations were carried out for two extreme cases, the bone material of which was assumed to be

- 1 Solid cortical bone (infinite homogeneous elasticity)
- 2 Two cortical layers with a hollow intermediate space (stepwise elasticity)

Case 1 On the basis of assumption 1 the model shown in Fig. 11 is used to calculate the deflection curve. In this case the deflection caused will obey the following differential equation

$$\frac{DE}{dx^4} + 4n^4y = 0$$

$$\text{where } \frac{C}{EI} = 4n^4$$

C = spring constant of elastic support
 EI = bending resistance of nail

Case 2 On the basis of assumption 2 above the model shown in Fig. 12 is used to calculate the deflection curve.

The loading case defined according to this figure with the load and moment applied to the end point is conveniently treated in parts according to Fig. 13.

Fig. 11 Model according to Case 1 (Homogeneous cortical bone)

Fig. 12 Model according to Case 2 (Two cortical layers with hollow intermediate space)

Fig. 13 Case 2 divided into three parts

Calculations

Equations for each partial loading case are obtained by superposition of the elementary cases for concentrated force and moment according to Hetenyi *Beams on elastic foundation*. By constructing boundary conditions the true deflection curve can be calculated. When the form of the curve has been obtained interest is concentrated on the most critical factor for the bone material, i.e. the point of maximum deflection.

Maximum deflection is obtained in the actual loading cases at that point where the force and moment are concentrated, i.e. at the external edge of the bone.

Formulae are derived for calculation of the edge deflection as a function of the following parameters

- 1 Modulus of elasticity of the bone
- 2 Spring constant of the bone
- 3 Moment of inertia of the nail
- 4 Modulus of elasticity of the nail

1 The modulus of elasticity, E_b for cortical bone, varies within wide limits and is strongly dependent on the type of loading (Sedlin, 1965) For these approximate calculations, a mean value between the moduli of elasticity for tension and for compression has been used, viz $E_b = 1075 \text{ kp/mm}^2$

2 The spring constant (C) is calculated according to a special model $C = k E_b$ where k is a constant The value of the constant varies with certain shape factors and has been calculated to lie within the range $2.0 > k > 1.6$ To calculate the deflection of the edge in the acetabulum the value $k = 1.75$ is used

3 The three-flanged nail of the Stryker J-type used for calculations and experiments has a moment of inertia of 140 mm^4

4 The nail is made of stainless steel with a modulus of elasticity $E_s = 21\,000 \text{ kp/mm}^2$

The Influence of Nailing Depth on Deflection of Edge

Assuming according to Case 1 (solid cortical bone) the deflection of the edge is calculated for a given force and moment as a function of the length ($\approx L$) of the part of the nail which is inserted into the material The result of these calculations shows that when a certain depth has been reached only a very slight improvement will be achieved by increasing the depth Thus, an improvement of only 5 per cent will be obtained if L is increased from 22 mm to infinite depth With decreasing nailing depth the deflection of the edge will increase rapidly (Fig. 14)

Assuming, according to Case 2 (two cortical layers with a hollow intermediate space) the deflection of the edge is calculated as a function of the thickness of the cortical layers and of the distance between them

According to the principle of superposition complete calculations can be carried out for force and moment separately and the results superimposed in the final calculations

In order to obtain an unambiguously defined quantity as a result the separate deflections are related to the deflection obtained using infinite homogeneous elasticity This involves defining the quotients

$$\text{for the force } R^P = \frac{\delta_0^P}{\delta_0^P(\infty)} = - \frac{\delta_0^P}{P_0} \\ 2n^3 EI$$

Fig 14 — — — — R^P — — — — R^M Improvement in percentage (diminished edge deflection) with increasing nailing depth according to Case 1

$$\text{for the moment } R^M = \frac{\delta_0^M}{\delta_0^M(\infty)} = \frac{\delta_0^M}{\frac{M_0}{2n EI}}$$

Calculations are performed assuming constant parameters the values of which are discussed above

$$E_b = 1075 \text{ kp/mm}$$

$$C = 175 \times E_b = 1880 \text{ kp/mm}$$

$$n = 0.1125$$

The results are tabulated in Table VI. The curve for a cortical layer thickness $a = 2.5 \text{ mm}$ is selected as a basis and the quotients relating the other curves to this basis curve are formed. The table of force values shows that the quotients of the variables $(b-a)$ are almost the same for each curve. This implies that only the exact form of the basis curve is reported together with a comparison curve for the quotients as a function of a values (Fig 15).

The table of values of moment shows that a corresponding relation does not exist. For the different a values separate curves are plotted (Fig 16). To obtain the intermediate a values interpolation has to be made.

Under the assumption that the bone obeys Hooke's law the values R^P and R^M are calculated from the curves of force and moment quotients. These are converted to a coefficient which constitutes the direction coef

$$\delta_0 = \delta_0^I + \delta_0^M$$

$$\delta_0^P = \frac{R^P}{2n^3 EI} \times P_0$$

$$\delta_0^M = \frac{R^M}{2n^3 EI} \times M_0$$

M_0 is converted to $M_0 = L \times P_0$

from which is obtained $\delta_0 = (K_0^P + K_0^M) \times P_0$

Fig. 15 a) Basis curve for R^p and cortical layer $a = 2.5$ mm
b) Comparison curve for the quotients as a function of a values

The influence on the edge deflection of a variation of the modulus of elasticity is shown in Diagrams 15 and 16. It is here seen that the values of R^p are increased by approximately 7 per cent when changing n from 0.1124 to 0.1045. The R^p values are increased by approximately 15 per cent when changing n from 0.1124 to 0.0972. These changes of the n value correspond to a change of the elastic modulus for cortical bone in the range of 1075—600 kp/mm.

Fig 16 Edge deflection as a function of bone layer thickness and distance between the layers for three different values of modulus of elasticity of bone. The two cortical layers are assumed to be of equal thickness and are designated a mm.

Conclusions

From the tables and diagrams showing the quotients R^P and R^M the following special relationship can be derived

1 For each individual value of the distance between the cortical layers $(b-a)$ the quotients become smaller with increasing cortical thickness. This implies that areas with thick cortical layers should be singled out for nailing.

2 As regards the influence of the forces it is found that with an increased distance $(b-a)$ from 20 mm to the distance giving R^P minimum, an improvement of less than 5 per cent is obtained.

The effect of the moment is altered however to a greater extent the thinner the cortical layer the greater is the change. The percentage improvement that can be obtained by increasing the distance $b-a$ from 20 mm to the distance which gives R^M minimum has been calculated in Table VII. The conclusion can be drawn that the nail should be inserted in such a direction that a large distance is obtained between the cortical surfaces at least 20 mm. The thinner the cortical layer the larger the distance must be.

TABLE VII

Percentage improvement that can be obtained by increasing the distance ($b-a$) from 20 mm to the distance which gives R^u_{min} , has been tabulated below as a function of the given parameters

Parameters	Cortical thickness mm	R^u_{min} at ($b-a$)	Obtainable improvement $\frac{R^u - R^u_{min}}{R^u}$ per cent
$I_b \sim 1075$ $n = 0.1124$	$a = 1.0$	90	60

	$a = 1.5$	85	60
	$a = 2.0$	65	50
	$a = 2.5$	58	39

Preliminary Experiments with Three Flanged Nail

A series of experiments was performed with the three flanged nail in order to find out the correlation between the theoretically calculated and the experimentally found values of the deflection of the edge and to determine the relation of the deflection to the nailing depth as carried into practice

The deflection of the edge was measured when the nail was subjected to bending stress inserted at different positions and depths into the acetabulum. Furthermore experiments were carried out with the nail subjected to torsional stress. The latter experiments were repeated with the nail driven through the femoral neck and head.

The specimen consisting of half of the pelvis was attached to the stand described previously. After preboring an Sv J nail was inserted into the desired direction and depth through the acetabulum.

Through a bore of the acetabular edge a metal tube was fitted with its orifice placed next to the edge of the bone above the nail (Fig. 17). A metal pin was introduced into the tube to contact the nail. When the nail was loaded the movement occurring at the edge of the bone was transmitted by the metal pin. The load was applied at right angles to the

Fig 17 Experimental device for determining edge deflection caused by bending stress on three flanged nail Nail inserted through two cortical layers Dial indicator attached to bone

longitudinal axis of the nail. The movement of the pin was read on a dial indicator. The entire measuring device was attached to the bone and, consequently, the error in measurement due to the elasticity of the attachment device was eliminated. Subsequently, the specimen was sawn through in the direction of the nail, so that the thickness of the cortical layers concerned and the length of the nail tunnel could be measured. On the basis of these values, theoretical calculations were made on the direction coefficient of the deflection curve. The latter was then put into relation to that measured at the experiment.

The theoretically calculated and experimentally measured values of the direction coefficient of the deflection curve at varying nail depths and different cortical thicknesses are presented in Table VIII.

The theoretical values of the direction coefficient are generally lower than the experimental ones. The reason is that the bone material sometimes in practice deviates in a negative direction as compared to that of an ideal case accepted in theory.

When hammering in the three-flanged nail, small cortical fissures originating from the flanges regularly occur. This means that the connecting factor of the bone material will be inferior around the nail. In comparison with the ideal case as assumed in the theoretical analysis, the deviation will be negative.

TABLE VIII

Direction coefficient (K) of deflection curve
Experimental and theoretical values a, b and L measured in mm

k_{theor} (n=0.1125)	0.95 · 10 ⁻¹	1,27 · 10	0.89 · 10 ⁻²	0.87 · 10 ⁻²
k_{theor} (n=0.0845)	2.80 · 10 ⁻¹	3.83 · 10	2,28 · 10 ⁻²	2.14 · 10 ⁻²

In cases where the nail penetrated a posterior cortical layer extensive fractures sometimes occurred. This affected the securing and also had a negative effect on the measured values.

For the theoretical calculations a fixed value which more or less can deviate from the value of the individual specimen was also applied to the modulus of elasticity.

Temperature, humidity, loading speed and so on, are all factors affecting the elastic modulus (Sedlin 1965, Sedlin & Hirsch 1966, Hirsch & da Silva 1967). The conditions existing at the experiments may justify the use of values for elastic modulus which are in the lower range of those used for the theoretical calculations or even lower.

The influence of various material factors can be represented in the mechanical model by a variation of the n value. Table VIII shows the influence on the direction coefficient for a variation of the modulus of elasticity of cortical bone and of the elastic coupling in the material. Thus the spring constant ($C = k \cdot Eb$) varies in the range of 600–1880 kp/mm². All these factors are included in the parameter n.

The parameters n and I_s (the moment of inertia of the nail) are essential for the values of the coefficient of direction. Thus n is found in the second and the third potency through which even small changes will have a comparatively large effect on the result.

Fig. 19 presents the deflection of edge at various depths of nail insertion. The nail has been directed towards the body of the iliac bone and its point has not penetrated any part of the internal cortex. The diagrams show that the deflection of edge becomes much improved when the nailing

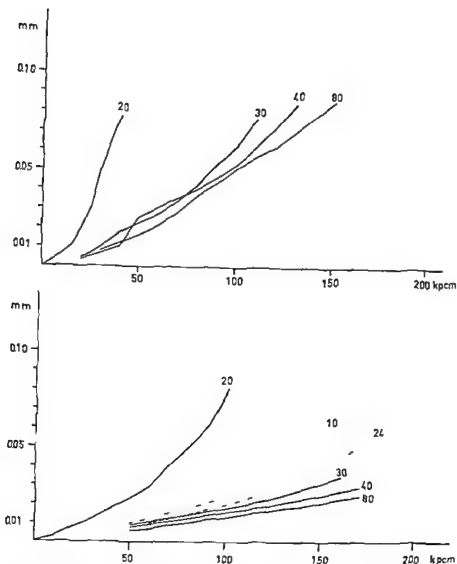

Fig. 18 Edge deflection caused by bending stress on three flanged nail
 - - - - - through two cortical layers ————— into body of iliac
 bone. Figures on curves designate nailing depth in mm.

depth is increased from 20 to 30 mm. A nailing depth exceeding 40 mm will only give slight improvement.

Experiments with Torsion Load

Experimental Device

The forces to which the nail has the least resistance act around the longitudinal axis of the nail.

A special torque transmission device was designed (Fig. 19) in order to find out the relation between nailing depth and deflection caused by torque.

Fig 19 Experimental device for determining deflection caused by torque on three flanged nail A = dial indicator B = lever pin transmitting movement to dial C = torque transmission device D = loading lever arm

The device consists of a shaft at one end mounted with a sleeve by means of a ball bearing. For transmitting the torque to the nail three screws are fitted in the sleeve. A lever is welded to the sleeve.

The three flanged nail was hammered into the desired depth of the mounted specimen. The sleeve of the torque transmission device was slipped over the head of the nail and their longitudinal axes were centered to each other. The shaft of the torque transmission device was fitted to the iron stand to prevent any bending moments. The screws in the sleeve head were tightened to grip the space between the flanges of the nail.

depth is increased from 20 to 30 mm. A nailing depth exceeding 40 mm will only give slight improvement.

Experiments with Torsion Load

Experimental Device

The forces to which the nail has the least resistance act around the longitudinal axis of the nail.

A special torque transmission device was designed (Fig 19) in order to find out the relation between nailing depth and deflection caused by torque.

Fig 19 Experimental device for determining deflection caused by torque on three flanged nail A = dial indicator B = lever pin transmitting movement to dial C - torque transmission device D = loading lever arm

The device consists of a shaft at one end mounted with a sleeve by means of a ball bearing. For transmitting the torque to the nail three screws are fitted in the sleeve. A lever is welded to the sleeve.

The three flanged nail was hammered into the desired depth of the mounted specimen. The sleeve of the torque transmission device was slipped over the head of the nail and their longitudinal axes were centered to each other. The shaft of the torque transmission device was fitted to the iron stand to prevent any bending moments. The screws in the sleeve head were tightened to grip the space between the flanges of the nail.

Experiments with Torsion Load

Experimental Device

The forces to which the nail has the least resistance act around the longitudinal axis of the nail.

A special torque transmission device was designed (Fig 19) in order to find out the relation between nailing depth and deflection caused by torque.

Fig 20 a b c Edge deflection caused by torque on three flanged nail

--- through two cortical layers — into body of iliac bone --- through femoral neck and head Figures on curves designate nailing depth in mm

The specimen was placed so that the nail and the longitudinal axis of the torque transmission device lay horizontally. The lever of the torque transmission device was adjusted to lie horizontally as well. By loading the lever, a gradually increasing torque was applied.

A small metal lever pin was attached to the nail perpendicularly and also placed horizontally at a fixed distance from the acetabular surface. A dial indicator was attached to the specimen by a metal rod so that its measuring point rested at right angles to the lever pin. By attaching the dial indicator to the specimen it was possible to evade potential errors in measurement caused by movements in the attachment of the specimen.

The dial indicator registered the movements of the lever pin in a tangential direction. The lever pin thus described a circular movement while the dial indicator recorded changes in the set direction. Thus, a systematical error in measurement was introduced which, however, with respect to the effective range, was considered to be of a negligible magnitude.

The lever arm also described a circular movement. This error in measurement is also systematical and can be neglected in the utilized effective range. The effect caused by the circular movements of the loading arm and the lever pin furthermore will counterbalance each other.

The distance between the attachment of the lever pin on the nail and the acetabular surface was measured. For measurement of the true torsion in the acetabular surface allowance must then be made for the torsion of the nail between the acetabular surface and the lever.

Measurement of Torsion of Nail

For determining the natural torsion of the nail the described torque transmission device was used. One end of the nail was fixed to a screw vice, and the other end to the torque transmission device. Two points of the nail were fitted with levers which each affected their dial indicator. A gradually increasing torque was applied and each indicator read. The natural torsion of the nail was thus determined to 14.16 per 0.1 kpm and per 10 mm of the nail. With satisfying accuracy the correction value 14 per 0.1 kpm and per 10 mm of the nail was used.

Torsion Experiments in Acetabulum

The described method was used for a series of experiments. In conformity with the bending stress there was a pronounced reduction of deflection of the edge when the nailing depth exceeded 20 mm. The value is however slightly higher in connection with torque as compared to bending stress. In reality a nailing depth of 4—5 cm should be attempted.

continued using a three flanged die. At the insertion of the nail the caput rested in a hemispherical metal cup or else in the acetabulum which thus offered adequate resistance. Despite this fractures of the cortical surfaces were regularly noted. The torque was applied to the nail from the caput side.

Curves of deflection are marked in the diagrams which were obtained at the experiments of the pelvis. The curves show that the resistance is about the same as for the greater depth on the pelvic side.

Conclusions

The theoretical analysis and the experiments performed show that if a single nail is selected as an osteosynthetic technique certain points should be carefully considered. As regards the nail it should have a great moment of inertia and shape properties which will give a minimum of fissures when penetrating the material. This also implies that the cortical layer must not be fractured when penetrated. As regards the edge deflection the nailing depth should theoretically amount to a minimum of 22 mm. The cortical layers should be as thick as possible.

The experiments have shown that there is a limit value for the nailing depth which exceeds 30 mm for bending stress and slightly higher for torsional stress. Thus the nailing depth should be at least 40 mm. The securing will then not be less than that on the femoral side.

This demand in reality means that only one direction of nailing is possible, i.e. when the nail reaches into the body of the iliac bone. Only then can sufficient depth be achieved. Furthermore in this direction a suitably dimensioned nail will be fixed between two cortical layers. This means that to the greater part it will rest in bone with cortical resistance properties. Finally with this direction there is no risk of fractures in the internal cortical layer.

Traumatic Effect of Three Flanged Nail

Nailing with a three flanged nail has revealed that there are great risks of fracturing the caput. The nailing has been done carefully to cause as small a trauma as possible. The caput rested in the acetabulum the preboring was done with great care and the nail tunnel was prepared with a die.

With the nail well centered into the collum and the caput the risk of fractures seemed small provided that the tip did not reach or penetrate the cortex of the caput. If this occurred fractures would regularly originate from the edges of the flanges. If the nail went obliquely through the caput the risk of fractures increased. This type of fracture usually appears as a

Fig 20 presents examples of deflection curves obtained at these experiments

The diagrams also include curves which were obtained with the nail in positions where it penetrated the posterior cortex. The thickness of bone then varied from 9 to 24 mm. The curves are at the same level as the one showing a nailing depth of 20 mm. Thus penetration of the posterior cortex does not necessarily mean improvement of the stabilization. This presents an uncertain factor depending on how the cortical surface is fractured when introducing the nail.

Torsion Experiments in Neck and Head of Femur

The method described was also used for torsion experiments with the nail, introduced just below the greater trochanter up through the femoral neck and head. The nail was inserted between 90 and 105 mm through the bone.

The nail tunnel was carefully prepared before inserting the nail. First a bore was drilled corresponding to the core of the nail. The preparation

These fractures are not visible on the radiographs partly because they are concealed by the opacity of the nail partly because they are not superimposed on normal radiographs

Arthrodesis with Three Flanged Nail

Arthrodesis was carried out in 35 specimens using the three flanged nail for the osteosynthesis. In five cases no measuring values could be obtained for statistical analysis because of undue complications with the specimens.

The preliminary experiments and the theoretical analysis of the three flanged nail reinforcement suggested a minimum nailing depth of 30 mm and a desired nailing depth of 40 mm. For the sake of relating these results to measurements on completed arthrodeses a series of 7 specimens was tested in which the nailing depth was less than 30 mm (Mean nailing depth 24.4 ± 3.9 mm). In the further experiments the nailing depth was at least 30 mm with a mean depth of 44 mm (± 10.4 mm).

When comparing these two depths the result is inferior with the more shallow depth the mean value for the deflection being considerably higher as also the mean rank (Tables XI and XII).

This confirms the results of the preliminary experiments.

For the comparative experiments the greater nailing depth was used except for specimen No. 75 which accordingly was excluded from the statistical analysis of the series.

In using the sign test the values are significantly inferior for all the loading directions as compared to three point fixation with N nails. The mean values of deflection are higher than for three point fixation and in ranking the mean rank places the method in a middle group (Tables X, XI and XII).

In order to find out if any loading direction was inferior as compared to the others the four loading directions within each specimen and on levels 6, 8 and 10 kp were subjected to ranking (Table IX). Loading in extension gives the highest total ranking sum while the other loading directions are about equal. In placing the loading directions in pairs according to the plane at which the movement takes place i.e. the frontal and the sagittal planes the fixation preventing movements in the sagittal plane will be inferior (flexion-extension). The movement will then act about an axis which will coincide with the longitudinal axis of the nail. In the minimum nailing depths (< 30 mm) however the movements of the individual specimens in abduction and adduction often appear to be greater than in flexion-extension.

In order to reach into the body of the iliac bone which is necessary to obtain the desired nailing depth the nail must be inserted 2–3 cm

below the greater trochanter, close to the anterior side of the femur at an angle of between 140 and 150 degrees (mean value $146^{\circ} \pm 4.6$). The nail penetrates the posterior upper lateral quadrant of the femoral head. Thus, it will pass the longitudinal axis of the femoral neck under an acute angle both in the frontal and the transversal planes. As a rule, it will lie very close to the posterior cortex of the neck, near the caput, which often results in longitudinal fractures.

The described position of the nail implies a slightly flexed position of the arthrodesis, a mean position between abduction and adduction and also a mean position for rotation. If the hip is flexed more, the insertion of the nail can be less anterior. In abduction and outward rotation there is an increased risk of the nail not running all the way through the bone of the collum-caput. From the point of view of nail position, the ideal position for arthrodesis is flexion, inward rotation and adduction. The nail will then lie optimally centered in the bone. From the clinical point of view, this is an impossible position.

Three-Flanged Nail and Plate

Osteosynthesis with nail and plate was performed according to Alvik (1961) (Fig. 22 a). The difficulty with the method is to obtain a good fit and satisfactory contact of the plate to the bone. The plate should cover the part from the ilium across the joint to the front side of the proximal femur. It is attached to the bone with several screws. A comparatively good fit of the plate is obtained by bending it properly. This may, increase the risk of corrosion (Venable & Stuck, 1948).

This technique was tried on 8 specimens. A comparison has been made with the three-point fixation with the three-flanged nail only and, finally, with a three flanged nail together with a lateral medial inserted N nail. In the sign test the three-flanged nail and plate showed significantly reduced movement for flexion-extension as compared with both the three point fixation and the simple three flanged nail (Table X). On the other hand, there was no significant difference between these methods as regards mobility with load in the abduction-adduction direction. As compared with the three-flanged nail and an N nail there was no significant differ-

below the greater trochanter, close to the anterior side of the femur at an angle of between 140 and 150 degrees (mean value $146^{\circ} \pm 4.6$). The nail penetrates the posterior upper lateral quadrant of the femoral head. Thus, it will pass the longitudinal axis of the femoral neck under an acute angle both in the frontal and the transversal planes. As a rule, it will lie very close to the posterior cortex of the neck, near the caput, which often results in longitudinal fractures.

The described position of the nail implies a slightly flexed position of the arthrodesis, a mean position between abduction and adduction and also a mean position for rotation. If the hip is flexed more, the insertion of the nail can be less anterior. In abduction and outward rotation there is an increased risk of the nail not running all the way through the bone of the collum-caput. From the point of view of nail position the ideal position for arthrodesis is flexion, inward rotation and adduction. The nail will then lie optimally centered in the bone. From the clinical point of view, this is an impossible position.

Three-Flanged Nail and Plate

Osteosynthesis with nail and plate was performed according to Alvik (1961) (Fig. 22 a). The difficulty with the method is to obtain a good fit and satisfactory contact of the plate to the bone. The plate should cover the part from the ilium across the joint to the front side of the proximal femur. It is attached to the bone with several screws. A comparatively good fit of the plate is obtained by bending it properly. This may, increase the risk of corrosion (Venable & Stuck 1948).

This technique was tried on 8 specimens. A comparison has been made, with the three-point fixation with the three flanged nail only and finally, with a three flanged nail together with a lateral medial inserted N nail. In the sign test the three-flanged nail and plate showed significantly reduced movement for flexion-extension as compared with both the three point fixation and the simple three flanged nail (Table X). On the other hand, there was no significant difference between these methods as regards mobility with load in the abduction adduction direction. As compared with the three-flanged nail and an N-nail there was no significant differ

1) Spfix screws

2) AO compression plate

ence in flexion and adduction. In abduction loading there was greater mobility while in extension loading the mobility was reduced. The mean values of deflection in 6, 8 and 10 kp were low (Table XI). In analysis ranking placed the method in the best group with respect to stability (Table XII). Thus it offers good stability but the application is rather difficult.

Three Flanged Nail and N nail

The experiments with the three-flanged nail resulted in great mobility when loading in the flexion-extension direction. The three-flanged nail will only have one point of fixation. The special shape of the cross section improves the resistance to bending and torsion stress as compared to a circular shape. Despite this the fixation with the three flanged nail could perhaps be improved by fixing an additional point in the contact surface between the caput and the acetabulum. This point should then be at a distance as far as possible from the three flanged nail. Thus the specific load in the bores will be reduced and more so the play in the acting point of the force. Actually the movement between the surfaces will decrease (Fig. 23).

On the basis of the shape of the pelvis there are consequently two possible positions for the complementary nail viz positions II and III (Fig. 24).

an N nail inserted from the greater trochanter and transversally directed into the acetabular part of the pubic bone the stabilization was considerably improved. The clinical procedure is also simple due to television roentgen and does not magnify the incision.

Three Point Fixation with Nails

In an earlier investigation (Graziani & Kalén 1965, Kalén 1965) a better result of stabilization was reported for arthrodesis of the hip by employing three thin nails of the N type as compared to fixation with a three-flanged nail. The N nail type was found to be superior to the three point fixa

Fig. 23 Deflection in short and long distances between points of fixation

The dimensions of the upper femoral end and of the three flanged nail prevent the use of a complementary nail of the same dimensions. The large moment of inertia of the three flanged nail also makes this unnecessary. Instead a nail of a thinner dimension is selected which can easily be placed inside the bone without affecting the large three-flanged nail. The two nails will penetrate the proximal femur about 10 cm. This will cause the nails to be well connected to each other. There is no additional advantage in letting the thinner nail run through a hole in the coarser one, as in Witt's double nail. A disadvantage with this arrangement is that the direction of the thin nail is set. Consequently it may be impossible to select a position which will give the best securing on the pelvic side.

Using an N nail in positions II and III a series of comparative experiments was carried out to establish the most suitable position for the nail. These experiments were made on 4 specimens. An N nail placed in position II (lateral medial position) gave a significantly better result than a nail in position III (main direction antero posterior) (Table X). The first position was selected for the subsequent experiments.

The technique was tried in a total number of 12 specimens. In comparison with the three point fixation there is no significant difference in any loading direction. As opposed to this there are significantly better values in all the loading directions as compared with the simple three flanged nail (Table X). In ranking this technique was placed in the best group from the point of view of stability with a mean rank below 4 (Table XII).

Thus it was found that simply by completing a three-flanged nail with

When compiling the experiments with the sign test a significantly improved fixation is found for all the load directions as compared to fixation with a three-flanged nail (Table X). The same result is found in comparison with three-point fixation with screws and with compression techniques. As compared to a three-flanged nail plus a lateral medial directed N nail there is no significant difference. In comparison with a three flanged nail and plate there is no significant difference in the load directions adduction abduction but negatively in flexion extension.

When compiling the method with the descriptive calculations there are low mean values for the deflection at 6, 8 and 10 kp. The ranking places the method in the best group with a mean rank of 3.50 (Tables XI, XII).

Variations of Three Points Fixation with Nails

Osteosynthesis with three nails was varied by substituting the N nail in position I for a nail of a larger dimension. An N nail of a 6 mm dimension was tested and also a triangular nail in principle a three flanged nail without flanges the latter having a maximum diameter of 8 mm.

On comparison between the different types of nail and the conventional ones used for fixation there is a significant difference in favour of a nail of the latter type in position I. However no significant difference could be found when the usual N nail in position I was replaced by a slightly coarser nail of the same type.

It should be pointed out that the coarser nails were inserted into the same tunnel as the thin N nail first introduced and then the specimen was re-tested. This will impair the conditions of the latter nails which to a certain extent explains the indemonstrable difference between the N nail of 4 and 6 mm dimensions.

Three Point Fixation with Screws

Osteosynthesis was performed according to Merle d'Aubigne (1964) with the nails in the positions recommended by him. The length of the screws was between 12 and 14 cm. The root diameter was 3.6 mm and the diameter over the threads 6 mm. The technique was carried out on ten specimens as comparative experiments (Fig. 22.1).

This technique was always performed first in order to ensure the best conditions for the screws. As a second technique the three point fixation with nails was performed. The results show significantly inferior values for the fixation with three screws in all loading directions. The descriptive calculations show a mean rank sum which ranges within higher values (Tables X, XII).

tion with Steimann pins. The difference can be explained by the circular cross section of the latter type.

The aim with fixation of this type is that each nail should lock the movement which occurs in a plane perpendicular to the longitudinal axis of the nail. The ideal is to place, if possible, the nails at an angle of 90 degrees. The maximum distance between each point of fixation in the spherical surface between the caput and the acetabulum is then obtained. The anatomical conditions are of 1 kind that the parts of the pelvis which offer the greatest nailing depth are placed so that their longitudinal axes will intersect each other at an angle of less than 90 degrees. On the femoral side, two of these directions will allow the nail to be inserted into the bone at a depth of between 8 and 10 cm, the third alternative of no less than 6 cm (Figs 24-6).

The outlined technique is in good accordance with the technological principle which expresses that for stabilization of a piece of material the points of fixation should be placed as far from each other as possible.

The thin nails of the N type have a diameter of 4 mm with a square cross section and slightly concave sides. Due to this dimension, a very small portion of the bone material is involved, and the technique has therefore been considered suitable to use as a reference method when evaluating the other techniques of osteosynthesis.

The position of the nails in three-point fixation is as follows: one nail is placed in the same position as for fixation with a three-flanged nail, i.e. into the body of the iliac bone (No. I, Fig. 24). A second nail is directed from the posterior part of the greater trochanter transversally and medially into the acetabular part of the pubic bone (No. II). The third nail is introduced slightly below the centre of and inside the intertrochanteric line. It takes a posterior course slightly medial and cranial into the spine of the ischium (No. III).

At the experimentally performed arthrodesis the insertion of nails in the described directions does not involve any difficulties. The small dimensions of the nails and their position will prevent them from contacting each other.

In clinical surgery there is no difficulty in placing nails Nos. I and II. Instead nail No. III which is directed to the spine of the ischium may involve a certain risk of nerve and vascular injury if the tip is uncontrollably hammered through the cortex of this area.

When introducing the nails into the femur the cortex has always been prebored with a suitably dimensioned drill. This is essential in positions I and III as these nails penetrate the cortex under an acute angle. The cortical layer into which nail No. I is inserted is furthermore rather dense.

When compiling the experiments with the sign test a significantly improved fixation is found for all the load directions as compared to fixation with a three flanged nail (Table X). The same result is found in comparison with three point fixation with screws and with compression techniques. As compared to a three-flanged nail plus a lateral medial directed N nail there is no significant difference. In comparison with a three flanged nail and plate there is no significant difference in the load directions adduction abduction but negatively in flexion extension.

When compiling the method with the descriptive calculations there are low mean values for the deflection at 6, 8 and 10 kp. The ranking places the method in the best group with a mean rank of 3.50 (Tables XI, XII).

Variations of Three Points Fixation with Nails

Osteosynthesis with three nails was varied by substituting the N nail in position I for a nail of a larger dimension. An N nail of a 6 mm dimension was tested and also a triangular nail in principle a three flanged nail without flanges the latter having a maximum diameter of 8 mm.

On comparison between the different types of nail and the conventional ones used for fixation there is a significant difference in favour of a nail of the latter type in position I. However no significant difference could be found when the usual N nail in position I was replaced by a slightly coarser nail of the same type.

It should be pointed out that the coarser nails were inserted into the same tunnel as the thin N nail first introduced and then the specimen was resected. This will impair the conditions of the latter nails which to a certain extent explains the indemonstrable difference between the N nail of 4 and 6 mm dimensions.

Three Point Fixation with Screws

Osteosynthesis was performed according to Merle d'Aubigne (1964) with the nails in the positions recommended by him. The length of the screws was between 12 and 14 cm. The root diameter was 3.6 mm and the diameter over the threads 6 mm. The technique was carried out on ten specimens as comparative experiments (Fig. 22.1).

This technique was always performed first in order to ensure the best conditions for the screws. As a second technique the three point fixation with nails was performed. The results show significantly inferior values for the fixation with three screws in all loading directions. The descriptive calculations show a mean rank sum which ranges within higher values (Tables X, XII).

tion with Steimann pins. The difference can be explained by the circular cross section of the latter type.

The aim with fixation of this type is that each nail should lock the movement which occurs in a plane perpendicular to the longitudinal axis of the nail. The ideal is to place, if possible, the nails at an angle of 90 degrees. The maximum distance between each point of fixation in the spherical surface between the caput and the acetabulum is then obtained. The anatomical conditions are of a kind that the parts of the pelvis which offer the greatest nailing depth are placed so that their longitudinal axes will intersect each other at an angle of less than 90 degrees. On the femoral side, two of these directions will allow the nail to be inserted into the bone at a depth of between 8 and 10 cm, the third alternative, of no less than 6 cm (Figs 24, 6).

The outlined technique is in good accordance with the technological principle which expresses that for stabilization of a piece of material the points of fixation should be placed as far from each other as possible.

The thin nails of the N-type have a diameter of 4 mm with a square cross-section and slightly concave sides. Due to this dimension a very small portion of the bone material is involved and the technique has therefore been considered suitable to use as a reference method when evaluating the other techniques of osteosynthesis.

The position of the nails in three point fixation is as follows: one nail is placed in the same position as for fixation with a three flanged nail i.e. into the body of the iliac bone (No. I, Fig. 24). A second nail is directed from the posterior part of the greater trochanter transversally and medially into the acetabular part of the pubic bone (No. II). The third nail is introduced slightly below the centre of, and inside, the intertrochanteric line. It takes a posterior course slightly medial and cranial into the spine of the ischium (No. III).

At the experimentally performed arthrodesis the insertion of nails in the described directions does not involve any difficulties. The small dimensions of the nails and their position will prevent them from contacting each other.

In clinical surgery there is no difficulty in placing nails Nos. I and II. Instead, nail No. III which is directed to the spina of the ischium may involve a certain risk of nerve and vascular injury if the tip is uncontrollably hammered through the cortex of this area.

When introducing the nails into the femur the cortex has always been prebored with a suitably dimensioned drill. This is essential in positions I and III as these nails penetrate the cortex under an acute angle. The cortical layer into which nail No. I is inserted is furthermore rather dense.

lization was not satisfactory with this technique. Already light loads caused considerable deflection. The sign test of this technique resulted in significantly inferior values as compared to stabilization with a three flanged nail and one N nail despite the fact that the compression method was carried out first. The range of the mean values of deflection is also high. In the statistical analysis of the technique, the ranking procedure gave the highest average ranking value (Tables X, XI, XII).

Compression Nail according to Fox

The osteosynthetic material consists of a nail with a square cross section and concave sides. The tip is designed to cause gradual scooping of the nail tunnel. There is also a locking washer to secure the tip of the nail inside the pelvis. It is coarser of a more simple design and easier to apply than the Axer nail. In this technique a plate is also fitted across the head of the nail. The plate is fixed to the femoral shaft with through screws. When the end nut is tightened, the compression is transmitted via this plate to the femoral portion. No helical spring is used (Figs 22 f, 25 b).

The method has been tested on 6 specimens; all comparative experiments with three point fixation.

In the sign test, there is a significantly higher deflection value with this method as compared to the three point fixation. However, the mean value of the deflection at 6, 8 and 10 kp loads ranges lower than the values obtained for the Axer technique. The explanation is probably that the dimensions and design are more correct (Tables X, XI).

At the ranking procedure, there is a comparatively high mean rank sum which places the method in the group of less satisfactory (Table XII).

Compression Nail according to Niebauer

The nail is three-flanged and has a slightly coarser dimension than the Axer nail. The locking washer on the inside of the pelvis also differs. The compression is brought about with a nut via a sleeve mounted on the head of the nail (Figs 22 g, 25 c).

The method was only tested in 3 specimens. In one of these, the stabilization only allowed a load of 4 kp in two directions. The stabilizing effect is clearly inferior as compared to the three-point fixation. Niebauer also recommends a complementary screw from the upper edge of the acetabulum through the caput in a caudal direction. The technique at present does not seem to be in clinical practice.

The advantage of the screw reinforcement is compared to that of the nail is that the screw is much more resistant to loading in axial direction. However, the bending resistance of a screw is less than that of a nail of the same dimension and further its resistance to torsional forces is lower. In the present case the stress to which the osteosynthetic material is subjected will mainly be in the form of bending and torsional stress. The property of the screw to bring about compression by prestress is here of less interest.

The load and muscular force, always cause compression. As the technique with nails gives better stabilization and is easy to apply, there is actually no reason to use screws instead.

Compression Methods

Four different methods for osteosynthesis with compression have been tried. In three of these, viz. the methods according to Axer, Fox and Niebauer, the same procedure, in principle, is utilized.

A nail is directed from the greater trochanter through the femoral neck and head, penetrating the acetabulum so that the tip will reach the true pelvis. It is secured with a locking device. A nut which is screwed on to the threaded end will then cause compression against the cortex of the femur. The femoral part will thus be pressed along the nail and there will be compression between the joint surfaces.

The fourth method according to Mac Kee consists of a coarse screw which is inserted into the acetabular roof.

These methods have been tried on a total of 23 specimens. The cartilage was carefully removed from the joint surfaces involved as when employing the methods of compression, an increased friction between the surfaces could be of importance for the efficiency of the fixation.

Compression Nail according to Axer

The osteosynthetic material consists of a short three flanged nail, a threaded pin which is screwed into the head of the nail, a locking device which is mounted over the tip of the nail and locking it against the cortical surface of the true pelvis. Furthermore, the outer end of the threaded pin is fitted with a plate of special design which rests against the femoral cortex. A spring to maintain the compression force, a locking washer and a nut, finally complete the device (Figs 22 e 25 a).

With osteosynthesis of this type there is a risk that the threads of the pin may catch in the plate which rests against the femoral cortex. It is necessary to take care that this does not happen as otherwise the compression in the arthrodesis will not be that intended.

The method has been tested in 8 specimens, 2 of which were comparative experiments with a three flanged nail and one transverse nail. The stabi-

lization was not satisfactory with this technique. Already light loads caused considerable deflection. The sign test of this technique resulted in significantly inferior values as compared to stabilization with a three flanged nail and one N nail despite the fact that the compression method was carried out first. The range of the mean values of deflection is also high. In the statistical analysis of the technique the ranking procedure gave the highest average ranking value (Tables X XI XII).

Compression Nail according to Fox

The osteosynthetic material consists of a nail with a square cross section and concave sides. The tip is designed to cause gradual scooping of the nail tunnel. There is also a locking washer to secure the tip of the nail inside the pelvis. It is coarser of a more simple design and easier to apply than the Axer nail. In this technique a plate is also fitted across the head of the nail. The plate is fixed to the femoral shaft with through screws. When the end nut is tightened the compression is transmitted via this plate to the femoral portion. No helical spring is used (Figs 22 f 25 b).

The method has been tested on 6 specimens all comparative experiments with three point fixation.

In the sign test there is a significantly higher deflection value with this method as compared to the three point fixation. However the mean value of the deflection at 6 8 and 10 kp loads ranges lower than the values obtained for the Axer technique. The explanation is probably that the dimensions and design are more correct (Tables X XI).

At the ranking procedure there is a comparatively high mean rank sum which places the method in the group of less satisfactory (Table XII).

Compression Nail according to Niebauer

The nail is three-flanged and has a slightly coarser dimension than the Axer nail. The locking washer on the inside of the pelvis also differs. The compression is brought about with a nut via a sleeve mounted on the head of the nail (Figs 22 g 25 c).

The method was only tested in 3 specimens. In one of these the stabilization only allowed a load of 4 kp in two directions. The stabilizing effect is clearly inferior as compared to the three-point fixation. Niebauer also recommends a complementary screw from the upper edge of the acetabulum through the caput in a caudal direction. The technique at present does not seem to be in clinical practice.

The advantage of the screw reinforcement as compared to that of the nail is that the screw is much more resistant to loading in axial direction. However, the bending resistance of a screw is less than that of a nail of the same dimension and further its resistance to torsional forces is lower. In the present case the stress to which the osteosynthetic material is subjected will mainly be in the form of bending and torsional stress. The property of the screw to bring about compression by prestress is here of less interest.

The load and muscular force, always cause compression. As the technique with nails gives better stabilization and is easy to apply, there is actually no reason to use screws instead.

Compression Methods

Four different methods for osteosynthesis with compression have been tried. In three of these, viz. the methods according to Axer, Fox and Niebauer, the same procedure, in principle, is utilized.

A nail is directed from the greater trochanter through the femoral neck and head penetrating the acetabulum so that the tip will reach the true pelvis. It is secured with a locking device. A nut which is screwed on to the threaded end will then cause compression against the cortex of the femur. The femoral part will thus be pressed along the nail and there will be compression between the joint surfaces.

The fourth method according to Mac Kee consists of a coarse screw which is inserted into the acetabular roof.

These methods have been tried on a total of 23 specimens. The cartilage was carefully removed from the joint surfaces involved as when employing the methods of compression, an increased friction between the surfaces could be of importance for the efficiency of the fixation.

Compression Nail according to Axer

The osteosynthetic material consists of a short three flanged nail, a threaded pin which is screwed into the head of the nail, a locking device which is mounted over the tip of the nail and locking it against the cortical surface of the true pelvis. Furthermore the outer end of the threaded pin is fitted with a plate of special design which rests against the femoral cortex. A spring to maintain the compression force, a locking washer and a nut finally complete the device (Figs 22 e 25 a).

With osteosynthesis of this type there is a risk that the threads of the pin may catch in the plate which rests against the femoral cortex. It is necessary to take care that this does not happen as otherwise the compression in the arthrodesis will not be that intended.

The method has been tested in 8 specimens. 2 of which were comparative experiments with a three-flanged nail and one transverse N nail. The stabi-

lization was not satisfactory with this technique. Already light loads caused considerable deflection. The sign test of this technique resulted in significantly inferior values as compared to stabilization with a three flanged nail and one N nail despite the fact that the compression method was carried out first. The range of the mean values of deflection is also high. In the statistical analysis of the technique the ranking procedure gave the highest average ranking value (Tables X, XI, XII).

Compression Nail according to Fox

The osteosynthetic material consists of a nail with a square cross section and concave sides. The tip is designed to cause gradual scooping of the nail tunnel. There is also a locking washer to secure the tip of the nail inside the pelvis. It is coarser of a more simple design and easier to apply than the Axer nail. In this technique a plate is also fitted across the head of the nail. The plate is fixed to the femoral shaft with through screws. When the end nut is tightened the compression is transmitted via this plate to the femoral portion. No helical spring is used (Figs 22 f, 25 b).

The method has been tested on 6 specimens, all comparative experiments with three point fixation.

In the sign test there is a significantly higher deflection value with this method as compared to the three point fixation. However the mean value of the deflection at 6, 8 and 10 kp loads ranges lower than the values obtained for the Axer technique. The explanation is probably that the dimensions and design are more correct (Tables X, XI).

At the ranking procedure there is a comparatively high mean rank sum which places the method in the group of less satisfactory (Table XII).

Compression Nail according to Niebauer

The nail is three flanged and has a slightly coarser dimension than the Axer nail. The locking washer on the inside of the pelvis also differs. The compression is brought about with a nut via a sleeve mounted on the head of the nail (Figs 22 g, 25 c).

The method was only tested in 3 specimens. In one of these the stabilization only allowed a load of 4 kp in two directions. The stabilizing effect is clearly inferior as compared to the three-point fixation. Niebauer also recommends a complementary screw from the upper edge of the acetabulum through the caput in a caudal direction. The technique at present does not seem to be in clinical practice.

The advantage of the screw reinforcement is compared to that of the nail is that the screw is much more resistant to loading in axial direction. However the bending resistance of a screw is less than that of a nail of the same dimension and further its resistance to torsional forces is lower. In the present case the stress to which the osteosynthetic material is subjected, will mainly be in the form of bending and torsional stress. The property of the screw to bring about compression by prestress is here of less interest.

The load and muscular force always cause compression. As the technique with nails gives better stabilization and is easy to apply, there is actually no reason to use screws instead.

Compression Methods

Four different methods for osteosynthesis with compression have been tried. In three of these, viz. the methods according to Axer, Fox and Niebauer, the same procedure in principle is utilized.

A nail is directed from the greater trochanter through the femoral neck and head penetrating the acetabulum so that the tip will reach the true pelvis. It is secured with a locking device. A nut which is screwed on to the threaded end will then cause compression against the cortex of the femur. The femoral part will thus be pressed along the nail and there will be compression between the joint surfaces.

The fourth method, according to Mac Kee, consists of a coarse screw which is inserted into the acetabular roof.

These methods have been tried on a total of 23 specimens. The cartilage was carefully removed from the joint surfaces involved as, when employing the methods of compression, an increased friction between the surfaces could be of importance for the efficiency of the fixation.

Compression Nail according to Axer

The osteosynthetic material consists of a short three flanged nail, a threaded pin which is screwed into the head of the nail, a locking device which is mounted over the tip of the nail and locking it against the cortical surface of the true pelvis. Furthermore the outer end of the threaded pin is fitted with a plate of special design which rests against the femoral cortex. A spring to maintain the compression force, a locking washer and a nut finally complete the device (Figs 22 e 25 a).

With osteosynthesis of this type there is a risk that the threads of the pin may catch in the plate which rests against the femoral cortex. It is necessary to take care that this does not happen as otherwise the compression in the arthrodesis will not be that intended.

The method has been tested in 8 specimens, 2 of which were comparative experiments with a three flanged nail and one transverse N nail. The stabi-

Fig 25 a—d Construction drawings of tested compression devices The measurements are expressed in millimeters

Compression Screw according to Mac Kee

The screw is inserted through the collum/caput and screwed into the acetabular roof reaching a depth of 2.5 cm. Only the part on the acetabular side is threaded with wide threads while the part of the screw in the femoral portion is smooth cylindrical. Also here there will be compression by means of a nut fitted on to the threaded outer end of the nail.

The method was tried in 6 cases as comparative experiments to the three point fixation. Two of these however had to be excluded as sufficient fixation for minimum loads could not be obtained. Only in one case were all four loading directions recorded with 4, 6 and 8 kp respectively (Figs 22 h, 25 d).

At the sign test the values of deflection were significantly higher as compared with the three-point fixation (Table X). The mean values obtainable for the deflection were high (Table XI). Due to the low number of observation ranking could not be calculated for loads of 6, 8 and 10 kp. As the stabilization in the experiments was poor there was no reason to increase the series. The poor stabilization depended on insufficient securing to the acetabulum, a short portion of the screw inserted into spongy bone and on the circular section of the screw. The first condition is the reason for an inferior preventive effect of the movement in abduction and adduction loading, the latter refers to the flexion extension loading.

In loading where the movement will occur close to the longitudinal axis of the screw i.e. mainly flexion extension, the counteracting force will only

be the friction force between the joint surface (primarily increased through compression) and friction between the screw threads and the bone in the acetabulum

Summary

In summary none of the tested methods of compression with nail or screw offered stabilization to a degree which could be expected. Stabilization with compression should theoretically give a better result than without. The reason of this not being the case may depend on the quality of the utilized bone on the pelvic side. The average thickness of the bone layer penetrated on the pelvic side was for the Axer nail 17 mm with a variation ranging between 11 and 27 mm and for the Fox nail 16 mm with a variation between 11 and 20 mm. As the nails in a small area inside the locking plate lack flanges a few additional millimeters are lost because the nail is pulled back at the compression (Fig. 26). The cortical layer of the pelvis is thin within the area concerned and not of the quality which for instance is found on the femoral side where the nail is inserted. Thus the bone cannot always resist the great stress concentration which will occur. Especially the curved locking plate used for the Niebauer nail causes impression in the underlying bone when subjected to compression. It should also be pointed out that the joint surfaces around the nail which are compressed against each other are not plane but spherical with a sometimes varying

F 27 Position of displacement gauges when testing AO compression plate

does not always allow the plate at the attachment to the ilium to be fitted in close contact to the bone. The bone to which it is screwed is of a thin dimension and has lower resistance properties than for instance the sturdy cortex of the femoral shaft. De Palma (1962) complained of the difficulty in obtaining a satisfactory attachment for screws in this region and instead recommended through bolts. The applied compression may partly compensate the inferior attachment but for example in abduction load the compression force will be reduced between the contact surfaces in general and in extension flexion load within certain areas.

As regards the contact surfaces the ilium will after osteotomy offer a very narrow bone area for contact with the surface of the caput. The caput will thus balance on this narrow bone surface when compression is applied. The contact surface of the ilium can be increased by placing the osteotomy on a more proximal level but as this is done the contact surface of the caput will be reduced accordingly.

The bone surfaces which are to be compressed will also lie at a great distance from the plate which causes compression.

Finally the osteotomy performed dorsally to the acetabulum will leave

flanges of the nail to the external cortical surface of the pelvis and its spongy bone. Finally, the torsion stress may be transmitted via the stop plate to the internal cortex. This is especially pronounced in using the Fox and Niebauer nails while, contrary to this, the locking plate in Axer's technique allows the nail to turn freely.

In all the experiments these compression methods were inferior to the reference method. In analysis the ranking procedure revealed that the compression methods do not offer better stabilization than an adequately fitted three flanged nail.

Arthrodesis with Compression Fixation according to AO

Arthrodesis was performed by the use of the technique described by Muller in the AO-Bulletin September 1967. With this technique the osteotomy of the pelvis is made horizontally at the level of the upper acetabular edge and releasing a segment of the upper part of the caput. The caput is displaced medially so that its planed upper surface will contact the bone surface of the ilium medial to the acetabulum. Part of the greater trochanter is removed by saw and then a specially designed cross plate is screwed on to the outside of the ilium so that the plate will contact the proximal femoral end laterally. Compression is applied by using AO's compression device and then screwing the plate to the femoral shaft (Fig. 22 j).

As the caput and the acetabulum are not kept intact when this technique is used, the earlier measuring technique was not applicable. Thus comparative experiments could not be executed either. The measurements were performed with three measuring calipers, fitted according to Fig. 27.

Due to pelvic osteotomy the pelvis could not be fixed in the same way as in earlier experiments. The ilium was instead fixed by means of polyester. The osteosynthesis leaves the entire ischio pubic portion of the acetabulum unstabilized.

Measurements were performed in three cases. In all the cases there was a certain amount of mobility in all the four tested load directions. The lowest reading was obtained for adduction load which was expected, as there will then be a force component in a direction which will increase the compression.

Digrams, (Fig. 28), exemplify the recorded movement in the three transducers with increasing load in the four tested load directions. Thus a total movement as S_m is not reported as in earlier diagrams. No relevant comparison with these values can consequently be made. It has merely been established that the method will not give rigid fixation.

Certain fixed factors may thus be involved. The design of the plate

Besides a form factor the properties of the nail are determined by a material factor namely the physical properties. Due to the demands made on the corrosive resistance the selection in reality is limited stainless steel vitallium titanium. For the experimental nail stainless steel was selected.

The moment of inertia of the nail completely depends on the form factor. It is defined for the perpendicular cross between the axes as follows

Moment of inertia with respect to x axis
$$I_x = \int_A y^2 dA$$

With respect to y axis
$$I_y = \int_A x^2 dA$$

The designed nail will according to the dimensions in Fig. 29 receive a moment of inertia amounting to 350 mm⁴ (compare the Sv J nail 140 mm⁴).

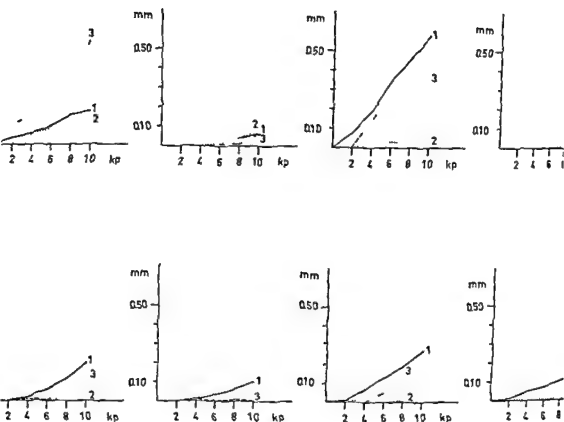

A cross section which gives a large moment of inertia in certain directions is the H form. It has been utilized previously for nail designs by Frankel (1960) and Laing & O'Donnell (1961). This section however causes difficulties in shaping the tip as the aim is to create as small a nailing in resistance as possible. Furthermore it may also involve a chiselling effect in the bone.

To obtain equal resistance of the nail in various directions it is necessary that its properties be uniform and therefore the design should be quite symmetrical if possible. The moment of inertia will then be constant in all the directions. A four flanged section is consequently preferable. The solid bone lying between the flanges will diminish by an increased number of flanges. An optimal relation between the number of flanges and the dimensions of the intermediate bone area should be attempted.

By finishing each flange with a circular segment instead of a pointed angle the moment of inertia will increase and at the same time the chipping effect will be reduced.

Due to the shape of the bone in that particular area a nail dimensioned 12 mm was selected. It is slightly smaller than the conventional Sv J nail.

To reduce the risk of fissures occurring along the flanges of the nail at the insertion the tip of the nail also has a special design. The nail has been extended from its middle to a circular tip in order to fit in a bore of the same dimension. The tip of the flanges have been guided back in relation to each other so that they will each rest against the bone surface. This means that a plane through the tips of the flanges will be at an angle of 145 degrees against the longitudinal axis of the nail. This will prevent the nail from sliding along the cortical surface. Furthermore the tip of each flange is shaped as a cross ground edge directed slightly towards the centre of

Figs 28 AO compression plate Experiments 109 and 112 The diagrams show displacement in gauges in positions according to Fig 27

large, open spongy bone surfaces which are not utilized for compression but clinically will be the source of extensive bleeding

Nail Design

The experiments which were performed on the basis of the theoretical analysis of the three-flanged nail show slightly higher values for the edge deflection than the theoretical values

The reason is mainly the impaired resistance resulting from the fractured bone connected with the insertion of the nail. The properties of the nail furthermore, are also decisive for the result. The moment of inertia of the nail is an important factor. It should be as large as possible. The dimensions of the nail should be such that it will remove as little as possible of the bone material. Finally, the anatomical shape of the bone areas concerned is a factor to consider when dimensioning the nail.

Besides a form factor the properties of the nail are determined by a material factor namely the physical properties. Due to the demands made on the corrosive resistance the selection in reality is limited: stainless steel, vitallium, titanium. For the experimental nail stainless steel was selected.

The moment of inertia of the nail completely depends on the form factor. It is defined for the perpendicular cross between the axes as follows:

Moment of inertia with respect to x axis
$$I = \int_A y^2 dA$$

With respect to y axis
$$I_y = \int_A x^2 dA$$

The designed nail will, according to the dimensions in Fig. 29, receive a moment of inertia amounting to 350 mm^4 (compare the Sv J nail 140 mm^4).

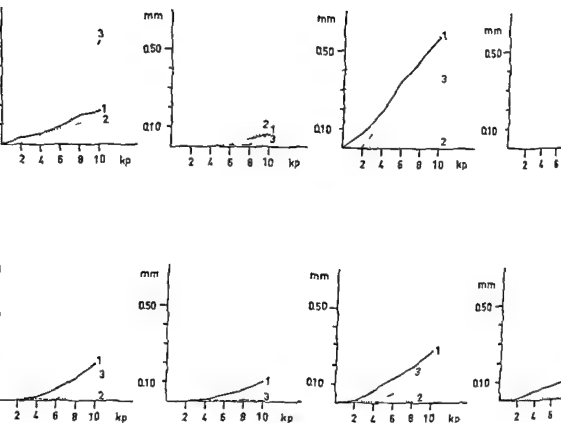

A cross section which gives a large moment of inertia in certain directions is the H form. It has been utilized previously for nail designs by Frankel (1960) and Laing & O'Donnell (1961). This section, however, causes difficulties in shaping the tip as the aim is to create as small a nailing in resistance as possible. Furthermore, it may also involve a chiselling effect in the bone.

To obtain equal resistance of the nail in various directions, it is necessary that its properties be uniform and therefore the design should be quite symmetrical, if possible. The moment of inertia will then be constant in all the directions. A four-flanged section is consequently preferable. The solid bone lying between the flanges will diminish by an increased number of flanges. An optimal relation between the number of flanges and the dimensions of the intermediate bone area should be attempted.

By finishing each flange with a circular segment instead of a pointed angle, the moment of inertia will increase and at the same time the chipping effect will be reduced.

Due to the shape of the bone in that particular area, a nail dimensioned 12 mm was selected. It is slightly smaller than the conventional Sv J nail.

To reduce the risk of fissures occurring along the flanges of the nail at the insertion, the tip of the nail also has a special design. The nail has been extended from its middle to a circular tip in order to fit in a bore of the same dimension. The tip of the flanges have been pulled back in relation to each other so that they will each rest against the bone surface. This means that a plane through the tips of the flanges will be at an angle of 145° against the longitudinal axis of the nail. This will prevent the nail from sliding along the cortical surface. Furthermore, the tip of each flange is shaped as a cross ground edge directed slightly towards the centre of

large, open spongy bone surfaces which are not utilized for compression but clinically will be the source of extensive bleeding

Nail Design

The experiments which were performed on the basis of the theoretical analysis of the three-flanged nail show slightly higher values for the edge deflection than the theoretical values

The reason is mainly the impaired resistance, resulting from the fractured bone connected with the insertion of the nail. The properties of the nail, furthermore, are also decisive for the result. The moment of inertia of the nail is an important factor. It should be as large as possible. The dimensions of the nail should be such that it will remove as little as possible of the bone material. Finally the anatomical shape of the bone areas concerned is a factor to consider when dimensioning the nail.

(Compare Fig 21)

In order to create as equal conditions as possible it was decided that each nail would be tested on the right left sides of the same specimen. Four of these experiments were performed. It was found however that the specimen factor by no means was eliminated by this. Furthermore there were

Fig 29 Construction drawing of experimental nail The measurements are expressed in mm

the nail When the nail is inserted, this edge will chisel out small fragments of bone Inside this edge at an angle of 90 degrees the flange itself is ground to an edge At the insertion small fragments of bone will be chiselled out and guided into the groove between the external coarser edge of the flanges and the centre of the nail They will accumulate here and definitely improve the securing of the nail

Testing of Experimental Nail

The earlier investigations showed that the three flanged nail combined with a thin transversal nail gave a very good primary fixation Thus there was no significant difference as compared to the three-point fixation with thin nails The purpose of the new designed experimental nail was to replace it for the three-flanged nail used in this method of stabilization Bearing in mind the disadvantages of the three-flanged nail the efficiency of the nail joint should gain

So that any difference between the experimental nail and the three flanged nail could be determined in practice it would have been advantageous to compare measurements with both nails tested on the same specimen As both nails however do not differ much with respect to dimension, and the position of both nails should be in good accordance, an experiment of that type would not be just The nail tried first will actually give such a loss of bone substance that the securing conditions for the following nail will be very poor

difficulties in obtaining whole pelvic specimens to the required extent

As direct comparative experiments could not be carried out, a series was tested using the experimental nail with an N nail and with the three-point fixation as a reference method. This series includes ten specimens. On each specimen osteosynthesis was first done with three N nails. Then the nails in positions I and II were removed (Fig. 22 b), and the experimental nail was inserted into position I.

In assessing the measured results and carrying out the sign test, there is a significantly greater mobility with three-point fixation in loading in flexion extension. On the other hand, there is no significant difference between the tested methods in abduction adduction loading (Table XIII). The mean values for S_{mix} are low, (Table XI) and ranking between certain methods places the method on the top (Table XIV).

In a test series with an Sv J-nail combined with a transversal nail and compared to three-point fixation, the sign test did not show any significant difference. By testing against the same reference method, as used here an indirect comparison can be made. As no direct comparative experiments were carried out the results cannot be regarded as statistically significant.

The results obtained, however, support the opinion that the new designed nail gives a better result than that of the conventional three flanged nail.

It can well be explained that an improvement is obtained in flexion extension in comparison with the three flanged nail but that no difference can be demonstrated in abduction adduction. Loads in the latter directions will cause considerable bending stress to the nail. The moment of inertia of the nail will be of great importance. However the moment of inertia for both nails is satisfactory in the loads concerned. When loading in flexion extension the nail will on the other hand transmit torsional stress. Any fractures of the bone emerging from the flanges will result in an impaired stability.

When performing arthrodesis it was established that the new designed nail had a reduced traumatic effect in the bone. In no case was there any

fracture of the caput or the acetabulum which was comparable to that caused by the three flanged nail (Fig 30) Subjectively it also gave a clear impression of penetrating the bone easier This also means that the risk of diastasis developing in the joint when the nail is inserted will be reduced By inserting the transversal N nail first the risk is completely eliminated

Electro-Mechanic Hammer

During the course of the experiments it was found that a special tool for insertion of the nails would be of advantage. The reason for this was to get a better control of the force of impact and an even distribution of the required energy. It was hoped that by this the traumatic effect of the nail would be further reduced. In co operation with the Division of Computer Research, Chalmers Institute of Technology, University of Goteborg an electro-mechanic hammer was thus designed and manufactured.

The principle of the design is depicted in Fig. 31. It consists of an electric coil inside which a core of soft iron slides. One end of the core is spring-loaded. When the coil receives an electric impulse, the soft iron core moves into the coil. This results in force of impact. The energy is transmitted to a hammering pin which is designed to grip the head of the nail. The nail is fitted to the pin by means of a sleeve which can be exchanged to fit all the nail dimensions. The sleeve is fitted to the front side of the hammer by means of a bayonet clutch.

A pulse generator, powered from 220 V mains, supplies the coil in the hammer with pulses of suitable frequency and energy. The pulse energy and thus also the force of impact is via a semiconductor-controlled rectifier operated with a pedal. The control unit is equipped with an illuminated main switch and a switch for the pulse frequency selector. The selector can be adjusted to produce 12.5 or 6.25 strokes per second. The hammer also has a switch to alter the force of impact: one position for nailing and one on a lower level for chiselling.

Within each position the force is controlled by means of the pedal. The controlling devices with which the tool is equipped ensures a lenient and rapid insertion of the nail. The tool can also be used for an effective and precise chiselling.

General Summary

There are many methods described in the literature dealing with the operative technique of arthrodesis of the hip. Certain problems have been of special interest. The position of the arthrodesis, the contact between the surfaces of the joint, bone grafting, additional subtrochanteric osteotomy and stabilization of the joint during the time of healing. In the latter case the techniques recommended vary extremely. However, the common opinion seems to be that some kind of osteosynthesis is necessary to obtain a successful result. The attitude towards a plaster hip spica varies depending on how reliable the internal fixation is considered to be. The evaluation of the stability of an osteosynthetic method is mainly based upon clinical observations.

The opinions are thus not unanimous with respect to the elaboration of osteosynthesis in arthrodesis of the hip. The aim with this study was to establish the extent of stabilization achieved by using various techniques of osteosynthesis and therefore experiments were carried out on autopsy specimens.

The simple nail reinforcement by the use of the three flanged nail was given special attention. A theoretical analysis shows that in ideal conditions a minimum nail depth of 3 cm in the pelvis is necessary for satisfactory stabilization. Furthermore, it is essential that the nail be maximally secured to a cortical bone.

The theoretical analysis served as a basis for an experimental study on the three-flanged nail. Thus the nail was inserted into the acetabulum at varying depths and in different directions. The nail was then subjected to bending moment and torque. The resulting deflection was recorded.

In comparing the values obtained in the theoretical analysis with those in the experimental investigation, the latter values were higher. In cases where the nail was inserted through an internal cortical layer, the analytical and experimental values deviated more than when the nail was placed between the cortical layers. The reasons are too small a nailing depth and fractures of the internal pelvic cortex. These fractures cause a poorer connection of the bone around the nail. The experiments revealed that a satisfactory result was obtained if the nail was inserted into the body of the iliac bone at a depth of approximately 4 cm. Further depth of the

Exp 103

that the nails are placed at a maximum distance from each other at optimal angles to each other and can be inserted to the greatest depth

When testing the three flanged nail a marked impairment of the stability could be found at nail depths below 3 cm. Therefore in the experiments where the three flanged nail was compared to the reference method only a greater nailing depth was accepted (mean value 4.4 cm). Even then the reference method was superior.

In order to improve the stabilization with a three-flanged nail this nail was combined either with an N nail, or with a plate. Two positions of the N nail were then compared. An N nail directed in a lateral medial direction into the acetabular portion of the pubic bone was superior to one inserted in an anterior posterior direction into the bone area at the spina of the ischium. At the continued experiments only the first mentioned position was therefore utilized. In comparison with the reference method there was no significant difference. The three flanged nail in combination with a sturdy metal plate which was attached to the iliac bone and the proximal end of the femur also gave results equal to the reference method.

In an experimental series various types of compression nails were tried. These were directed trans articularly into the pelvis and secured with a washer. None of the tested methods resulted in the desired stability. They were inferior to the reference method and even inferior to a three-flanged nail inserted at the recommended depth. The reason of this probably was that the bone layer on the pelvic side penetrated by the compression nails did not have the necessary resistance. The bone layer is too thin generally only about 15 mm and the cortex on the inside of the pelvis is weak.

A comparison was also made between three point nail fixation and three point screw fixation the result of which was in the negative for the screw. The screw is fit to resist axial tensile stress but of a corresponding nail dimension has a lower bending resistance and impaired ability to resist torque.

Thus the results were equal between the reference method the three flanged nail and plate and the three flanged nail and N nail. As the latter is easiest to apply there was reason to attempt improving on it. The disadvantage of the method is connected with the traumatic effect of the nail. The nail due to its design causes great resistance at the insertion. This results in diastasis of the joint when the nail penetrates the acetabulum. The bone layers which are passed may be fractured causing an impaired securing of the nail. In an attempt to improve these deficiencies an experimental nail was designed. By a special design of the tip of the nail and of the flanges the nail was easier to introduce and at the same time the risk of fissures occurring in the bone was diminished. Due to the design of

nail only gave an insignificant increase in stabilization. The nail then lay fixed between the cortical surfaces and could be regarded as secured to a bone with cortical resistance properties. In this position, the securing in the pelvis was not inferior to that on the femoral side.

Finally, these experiments also reveal that the three-flanged nail of the conventional type has a great tendency to causing fractures in the areas of bone through which it passes. The greatest risk is the passage through the femoral head, as almost without exception fractures occur. These appear as a fissure in the caput along the flange of the nail which is close to the surface or as a triangular fragment which is released. These lesions are generally not visible on the radiographs due to the opacity of the nail and the conventional projection.

A special measuring technique was elaborated in order to test the immediate stabilization obtained in autopsy specimens with various techniques of osteosynthesis in arthrodesis of the hip. The calculations demand that the movement between the joint surfaces at the acetabular edge should be measured at three points, each in two directions. Special extensometers were designed for this measuring. The arising movement was transmitted by these extensometers to electric impulses which via an amplifier were recorded.

The values obtained were concentrated to one value which represented the maximum movement. The measurements were performed during gradually increased loading of the femur in four directions of mobility: flexion, abduction, extension and adduction. By combining the values obtained for the maximum movement with the respective loads, diagrams were plotted which represent the movement in the arthrodesis as a function of the loading.

In several experimental series the various osteosynthetic methods were tried. For statistical reasons it was considered justified to perform comparative experiments on the same specimen. As a reference method, osteosynthesis with three Nystrom nails (N-nails) was selected. The reason for this was that the N-nail did not damage the bone in such a way that the results of the subsequent osteosyntheses would be affected negatively. The positions of the N-nails were selected on the basis of an earlier investigation. Thus one nail was inserted from a point below the greater trochanter upwards backwards into the body of the iliac bone. The other was directed from the upper part of the greater trochanter in a horizontal direction into the acetabular portion of the pubic bone. Finally the third was introduced from the front of the proximal part of the femur through the collum caput into the bone area at the spina of the ischium. By applying the nails in these positions, the skeleton can be utilized to a maximum. This means

the tip, the bone particles released at the insertion will be pressed in between the flanges and, as a consequence, the securing will improve. The nail has also a greater moment of inertia than that of the conventional three-flanged nail in spite of its thinner dimension.

In a series of experiments the experimental nail was tried together with a transversal N nail. The results were significantly improved in the loading directions which mainly cause torque; however, there was no significant difference in the loading directions which mainly cause bending stress as compared to the reference method. The result may be connected with the improved securing of the nail to the bone, which is obtained by eliminating the fractures emerging from the flanges. This improved securing can be expected to bring about a better stabilization with respect to the torque.

An electro-mechanic hammer was designed to further reduce the risks of fractures when the nail was inserted. The hammer allows an adjustment of both the frequency of the strokes and the force of impact. Consequently, the insertion of the nail can be fully controlled.

Conclusions

An experimental investigation was carried out on autopsy specimens for the assessment of the primary stability in arthrodesis of the hip. The following conclusions can be made:

Osteosynthesis with a trans-articular compression nail or a screw will give poor stabilization.

Osteosynthesis with a three flanged nail will give a better stabilization provided that the nailing depth is at least 4 cm into the body of the iliac bone.

Osteosynthesis with three Nystrom nails in described positions (three point fixation), three-flanged nail with a plate, and three flanged nail with one Nystrom nail in a described position will give good stabilization.

Osteosynthesis using three-point fixation with screws will result in an inferior stabilization, as compared to three point fixation with nails of the corresponding dimensions.

A very good stabilization was obtained with a new designed experimental nail in combination with one Nystrom nail in a described position. These devices offer less difficulties at the application as compared to many others.

the tip, the bone particles released at the insertion will be pressed in between the flanges and, as a consequence, the securing will improve. The nail has also a greater moment of inertia than that of the conventional three-flanged nail in spite of its thinner dimension.

In a series of experiments the experimental nail was tried together with a transversal N-nail. The results were significantly improved in the loading directions which mainly cause torque, however, there was no significant difference in the loading directions which mainly cause bending stress as compared to the reference method. The result may be connected with the improved securing of the nail to the bone, which is obtained by eliminating the fractures emerging from the flanges. This improved securing can be expected to bring about a better stabilization with respect to the torque.

An electro-mechanic hammer was designed to further reduce the risks of fractures when the nail was inserted. The hammer allows an adjustment of both the frequency of the strokes and the force of impact. Consequently, the insertion of the nail can be fully controlled.

Conclusions

An experimental investigation was carried out on autopsy specimens for the assessment of the primary stability in arthrodesis of the hip. The following conclusions can be made:

Osteosynthesis with a trans articular compression nail or a screw will give poor stabilization.

Osteosynthesis with a three-flanged nail will give a better stabilization provided that the nailing depth is at least 4 cm into the body of the iliac bone.

Osteosynthesis with three Nystrom nails in described positions (three-point fixation), three flanged nail with a plate and three flanged nail with one Nystrom nail in a described position will give good stabilization.

Osteosynthesis using three point fixation with screws will result in an inferior stabilization, as compared to three point fixation with nails of the corresponding dimensions.

A very good stabilization was obtained with a new designed experimental nail in combination with one Nystrom nail in a described position. These devices offer less difficulties at the application as compared to many others.
